Transplantations and restorative therapies for PD have a long history, dating to the 1970s, but are still only in use as part of clinical trials. In a randomized study of 40 patients with severe PD receiving either a transplant of human embryonic dopamine-neurons or a sham surgery, it was shown that the transplanted cells survived and resulted in some clinical benefit in younger but not older patients. Furthermore, clinical benefit and graft viability were sustained up to 4 years after transplantation and the imaging changes reliably correlated with clinical outcome over the post-transplantation time

course. In contrast, in another prospective 24-month double-blind placebo-controlled trial of fetal nigral transplantation in 34 patients with advanced PD, a slight treatment effect in patients with milder disease was observed. Some 56% of the transplanted patients however developed off-phase dyskinesia (Olanow et al., 2003). These dyskinesias were also described by other groups and can persist up to 11 years. Currently neural transplantation remains as an experimental therapy. Further studies are necessary to obtain objective evidence of benefit, define target patient population, determine the optimal cells for transplant and the exact brain target area for transplantation.

Surgical outcomes

Parkinson's disease

There is good long-term evidence on effectiveness of DBS to improve motor symptoms in advanced PD with significant benefits in tremor, rigidity, and bradykinesia. Typically, improvements in general motor state as measured by UPDRS-III of 50%, reduction in off-periods during the day by 70%, and prolongation of periods with good mobility of approximately 20% are expected (Alamri et al., 2015). Overall, tremor and rigidity show better long-term improvement than bradykinesia. Axial symptoms that respond to the Levodopa usually also improve. Furthermore, medication-related complications like motor fluctuations and dyskinesias decrease by 60–70% after STN DBS. Despite these benefits, the natural neurodegenerative course of PD does not appear to be altered by DBS and, thus in the long term, worsening of axial symptoms and akinesia should be expected. Cognitive decline is also unchanged reflecting the natural course of the disease. Nevertheless, a consistent marked motor improvement especially of tremor, rigidity, motor fluctuations, and dyskinesias have been reported in studies up to 5–10 years after STN DBS. Levodopa equivalent dose of parkinsonian daily medications can be reduced by 40–60% which is maintained after 5 years.

Recently it has been shown that motor improvements after STN DBS is not limited to patients with advanced PD. The randomized, prospective multicentre EARLYSTIM trial demonstrated favourable outcomes in the neurostimulation group. Given these results, especially early at the onset of disabling motor fluctuations, DBS has been advocated at an earlier stage in the disease process than the current practice. However, long-term outcome in this cohort is awaited (Schuepbach et al., 2013).

Non-motor symptoms (NMS) are common in PD patients and can have dramatic impact on patients' quality of life. Though DBS literature has primarily focused on motor symptoms, evidence indicates that STN DBS can improve NMS in selected patients (Witt et al., 2008).

Essential tremor

The short- and long-term benefits of DBS have been repeatedly demonstrated with significant resolution of upper extremity tremor reported in up to 90% of patients. Several studies have compared the clinical outcomes and complications related to DBS and thalamotomy in ET. Both methods produce near complete resolution of contra-lateral upper extremity tremor in approximately 60–90% of patients (Zhang et al., 2010). Long-term benefits are similar between both methods, with significant lasting improvement seen in the majority of patients although with both therapies, over time there may be a reduction in benefit in some patients. The primary difference between the two therapies is an increase in serious neurological complications associated with thalamotomy compared to DBS. Thalamotomy is currently only considered in selected patients with medication resistant disabling tremor who would not be good candidates for DBS either for medical issues precluding tolerance of the DBS hardware, known need for repeated MRI scanning, inability to comply with follow-up appointments for DBS programming and costs. In rare cases, an ET patient may not be able to tolerate DBS or thalamotomy due to increased surgical risk secondary to other medical conditions. In these cases, radiosurgical thalamotomy may be considered.

Dystonia

Ablative stereotactic surgery to treat dystonia has been performed in both the thalamus and the GPi. Outcomes have been difficult to assess due to lack of standardization of inclusion criteria, assessments, and surgical technique. Nevertheless, results of thalamotomy for primary and secondary dystonia have shown 25–100% improvement in 10/20 idiopathic cases and 25–100% improvement in 68% of 29 patients with secondary dystonia. However, significant side effects (15% hemiparesis and up to 56% dysarthria/dysphonia) have limited the use of this procedure. Buzaco has reported almost the same efficacy of pallidotomy compared to thalamotomy but less frequent complications with subsequent reports, confirming the efficacy of pallidotomy in alleviating the dystono-dyskinetic symptoms in patients with primary or secondary dystonia. No long-lasting complication is documented in any of these reports (Speelman et al., 2010).

The GPi is currently the target of choice for DBS surgery in dystonia, though thalamic and subthalamic nucleus stimulation have also been utilized. In primary generalized dystonia, a significant improvement of the motor and disability scores of the BFMRS has been reported (range 40–80%). Similar results have been described in patients with segmental dystonia. With a follow-up as long as 10 years, the pallidal DBS therapeutic effects appear stable. Patients with secondary dystonia represent a heterogeneous population and though it is accepted that, in general, secondary dystonia does not respond to DBS as well as primary dystonia, several reports showed satisfactory clinical outcome in many secondary dystonia, such as tardive dystonia. The discrepancy in the post DBS outcomes in this patient population when using validated movement disorder scales versus those measuring the quality of life/patient-reported outcomes, has encouraged the increasing use of the latter.

Controversies

DBS has been firmly established as an effective intervention for movement disorders for nearly three decades and thus controversies chiefly relate to differences in surgical technique rather than the efficacy:

- General vs. local anaesthesia—good outcome from DBS relies on accurate lead position within a very small, deep target. An awake patient allows for intraoperative macrostimulation through the

DBS lead to assess the optimal position for symptom relief and thresholds for avoiding side effects, and thus allows for immediate re-positioning of the electrode to a more effective target. However, an awake patient is required to be cognitively intact to perform mental tasks, cooperative and remain still for prolonged periods while in the 'off-state'. These latter concerns are removed with general anaesthesia; however, lead positioning is then reliant only on imaging targeting methods and intraoperative microelectrode recording. There has been no randomized controlled trial comparing outcomes for both techniques.

- Microelectrode recordings (MER)—is an electrophysiological technique of verifying the borders of a target nucleus using its firing pattern and characteristic signals. Recording is performed by inserting very fine tipped electrodes. However, MER necessitates expertise, expense, and additional operating time to an already prolonged procedure. There is also evidence that MER increases the risk of intracerebral haemorrhage. With improvements in surgical technique allowing for accurate image guided 'direct' targeting of the nuclei, the continued routine use of MER has been questioned by some surgeons.
- STN vs. GPi—The debate over whether to use GPi or STN DBS as the target for PD has stemmed from various studies that have shown varying degrees in outcome. Overall opinion over the past 10 years have been in favour of STN DBS for the majority of DBS candidates, while favouring GPi stimulation in the older patients, those with predominant dyskinesia, or those at risk of neuropsychiatric disturbance. More recent studies have shown comparable outcomes with both targets.
- Duodopa vs. DBS—Maintaining steady plasma concentrations of oral levodopa presents problems due to gastric emptying which results in fluctuating motor symptoms. With a reliable pharmacological profile and a portable delivery system, the use of intrajejunal L-dopa/carbidopa gel (Duodopa) has become an option in patients with motor fluctuations. Studies comparing Duodopa with DBS are limited, though one comparing the two interventions showed that the DBS group had significantly more improvement in dyskinesias duration and disability compared to duodopa (Merola et al., 2011). Although duodopa appears to be a promising alternative for PD patients, particularly in whom DBS is contraindicated, the large complication rates related to PEG tube insertion cannot be dismissed. The issue of costs is also an important one with duodopa being significantly more expensive than DBS.

Spasticity

John Goodden, Catherine Hernon, and Brian Scott

Introduction

This chapter reviews spasticity causes and treatments in adults and children. Due to the diversity of this subject, and the age range covered, it should be noted that some treatments covered in this chapter are only applicable for a limited group of patients.

Spasticity is the term used to describe an involuntary, velocity-dependent increase in muscle tone leading to increased resistance to movement. It arises as a result of upper motor neurone lesions (UMNL), which lead to loss or diminution of descending inhibitory influence on the alpha and gamma motor neurones. This is demonstrated by changes within the reflex arc, with loss of inhibitory input, leading to an exaggerated reflex. Depending upon the cause of the UMNL, the effects of spasticity may be seen in the upper or lower limbs.

Traditional descriptions of spasticity have used terms such as hemiplegia, diplegia, and quadriplegia to describe the distribution of the spasticity and the limbs involved. However, neurorehabilitation experts recommend that these terms are not used as they falsely suggest that the other limbs are unaffected, when they actually may be mildly affected. It is therefore preferred to state the mainly affected limbs (e.g. 'spasticity mainly affecting the legs' rather than 'diplegia').

Pathophysiological basis of spasticity

The pathophysiological changes in the brain and spinal cord that lead to spasticity are incompletely understood. However, it is thought to arise mainly from injury to the reticulospinal and corticospinal/pyramidal tracts and the spinal interneurons. The injury leads to a reduction in the inhibitory input to the spinal motor circuits with a consequent exaggeration of the reflex arc. Enhanced H-M ratios and F-wave amplitudes on neurophysiology testing provide evidence of this increase in motor neurone excitability.

Within the spinal cord, changes are seen in the excitability of the motor neurones, the interneurons, and reflex arc pathways. In the healthy subject, the 1a inhibitory interneurons mediate the reflex arc, receiving descending input from the descending corticospinal pathways as part of this action. Spasticity is seen when the interneurons are damaged, as well as when the descending input is reduced.

In the affected muscles, shortening and contracture commonly develop over time, but muscle spindle sensitivity is usually unaltered.

Clinical aspects of spasticity—aetiology

The causes of spasticity are congenital (cerebral palsy, spinal cord tethering/dysraphism) or acquired (stroke, trauma, tumour, demyelinating conditions, progressive neurodegenerative diseases, infections, and hydrocephalus and syringomyelia). Since spasticity arises from an UMNL, it would not be expected to result from a spinal injury below the conus medullaris. If the patient has suffered an acute UMNL, muscle tone is usually low with a flaccid paresis initially, before progressing to spasticity.

Cerebral palsy is the commonest cause of paediatric spasticity and multiple sclerosis (MS) is the commonest in adults.

Cerebral palsy has an incidence of 1 in 500 live births. It is a non-progressive condition, with a variety of clinical manifestations, including spasticity, dystonia, dyskinesia, and ataxia. While the brain lesion is static, the effects on the musculoskeletal system are often progressive because the muscles grow more slowly than the adjacent bones and also because of an imbalance of forces across the joints. These have deleterious effects on the shape of the developing bones and joints.

Multiple sclerosis is an immune-mediated, progressive degenerative condition with a variety of courses including relapsing-remitting and gradually/rapidly progressive. It occurs principally in people of a Northern-European origin, has a peak onset around age 30, and a female:male ratio of up to 3:1. The UK incidence has recently been estimated at 9.64 per 100 000 population, with a prevalence in England and Wales of 100–140 per 100 000 population, increasing to 170 in Northern Ireland, 190 in Scotland, 295 in Shetland, and 402 in Orkney.

Investigation, assessment, and diagnosis of spasticity

Patients presenting with spasticity need referral to and workup by a skilled physician, with a thorough assessment. This includes a detailed history and examination, baseline blood tests (including FBC/

UE) and blood/urine cultures to look for infection. Family history is particularly important for children when considering neurodegenerative conditions. Specialist investigations such as cerebrospinal fluid (CSF) analysis, MRI scanning, and EMG/EEG may also be required.

When a patient presents with a sudden exacerbation of their symptoms, the clinician needs to again undertake a detailed history and examination, blood tests, and urine cultures. Common factors causing deterioration include infection (especially urine or ear), medication changes, pain, pressure sores, constipation, occult fracture, foot/orthotic problems, DVT, stress, fatigue, and even cold weather.

A careful multidisciplinary team (MDT) assessment is required, including evaluation of which muscles are overactive and how the spasticity affects the patient throughout their daily life including self-care, mobility, sleep, and employment. A variety of scoring systems have been developed to document the extent of spasticity and functional limitation. The modified Ashworth Scale is the most commonly used tool to grade the extent of spasticity (Platz et al., 2005) (Table 77.1), but others such as the Tardieu score are also used. In addition, documentation of range of movement, muscle power, quality of life, function, and gait (if relevant) are required (Haley et al., 1992; Steinbok, 2001; Platz et al., 2005; Haugh et al., 2006; O'Brien and Park, 2006; Engsberg et al., 2007; Harvey et al., 2007: Khan, 2007; Delhaas et al., 2008; Gorton et al., 2009; Akerstedt et al., 2010, Gilmore et al., 2010; Ou et al., 2010; Dasenbrock et al., 2011; Reynolds et al., 2011; Tedroff et al., 2014). These assessments should be performed ahead of any planned intervention so the effects of the intervention can be evaluated.

For children with cerebral palsy, measures such as the Gross Motor Function Classification System (GMFCS) and Gross Motor Function Measure (GMFM) are useful tools to document and summarize a child's functional capabilities. The GMFCS is graded from 1 (independent) to 5 (wheelchair-bound) (see Fig. 77.1 and Table 77.2). The GMFM is a standardized observational instrument that has been designed and validated to measure change over time, helping to summarize this with a single score that can then be compared to chart their progress.

Table 77.1 The modified Ashworth Scale

Score	Description	Examination
0	No increase	Moves freely at any velocity
1	Slight increase	Catch and release or minimal resistance at end range
1+	Slight increase	Catch and release with minimal resistance through remainder of range of motion
2	More marked increase	Moderate resistance throughout range, but joint is easily moved
3	Considerable increase	High tone is present—joint is difficult to move
4	Severe increase	Affected joints are rigid-cannot be moved from flexed or extended position

Medical management of spasticity (including rehabilitation, physiotherapy, and occupational therapy)

The MDT managing spasticity should include a rehabilitation physician, physiotherapists, occupational therapy, and a variety of surgeons (neurosurgery, plastic surgery, orthopaedic surgery) (Park and Albright, 2006; Steinbok, 2006; Abbott, 2007; Ronan and Gold, 2007). It is important to carefully balance the control of spasticity against any side effects of doing so. Spasticity may be providing a positive impact in the patient's life as well as a negative one. For example, the spastic stiffness in a patient's legs may counteract the underlying weakness and allow them to walk; removing this spasticity may render them immobile.

Functional help can be provided via communication aids, splints, customized walking frames, and customized wheelchairs. The aim is to protect function and avoid/reduce the harmful effects of the spasticity and disability as a whole. Regular physiotherapy is central to this, to maintain flexibility and avoid the progression of muscle/tendon contracture formation. Occupational therapy and orthotic reviews are necessary to protect skin, and optimize splints and supports, maximizing function, and preventing pressure sore development. Finally, good bladder care is also vital to prevent recurrent infections (urinary tract infection is very common cause of spasticity exacerbation).

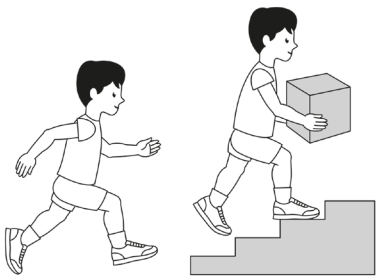
A variety of medical interventions can be undertaken to help limit the deleterious effects of spasticity. These treatments aim to improve tone, alleviate spasms, control gastrointestinal effects, and control bladder function.

Commonly used antispasticity medications include baclofen, dantrolene, tizanidine, and diazepam (Papavasiliou, 2009; Quality Standards Subcommittee of the American Academy of Neurology et al., 2010; Novak et al., 2013). Their side effects are varied but can include drowsiness, weakness, fatigue, sedation, and memory impairment. For these reasons they can be unpopular, especially if patients/carers read up about them prior to taking them.

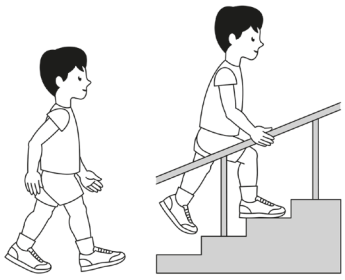
Baclofen is generally considered the mainstay of spasticity treatment, especially in cerebral palsy and spinal cord lesions. It acts via the pre- and postsynaptic $GABA_B$ receptors, reducing excitatory transmission of the α-motor neuron and decreasing nociception. It has good gastrointestinal (GI)-tract absorption but poor transfer across the blood–brain barrier. Therefore, high doses may be required before clinical effects are seen, creating a higher risk of side effects—including sedation, behavioural changes, confusion, ataxia, urinary frequency, and insomnia. Baclofen is started at low dose and gradually increased until benefits are maximized or side effects become troublesome. If it is being discontinued, this must be done gradually due to the risk of seizures, rebound hyperspasticity, or hallucinations.

Dantrolene is used for treatment of spasticity, cramps, and spasms. It acts by reducing depolarization-induced calcium influx into sarcoplasmic reticulum of striated muscle. Its GI absorption is incomplete, slow but consistent. Side effects include muscle weakness (making mobility more difficult), sedation, and hepatitis.

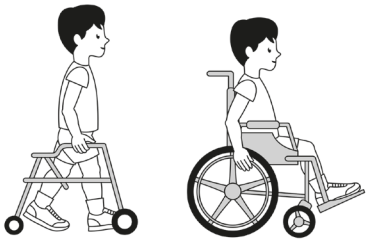
GMFCS E & R between 6th and 12th birthday: Descriptors and illustrations



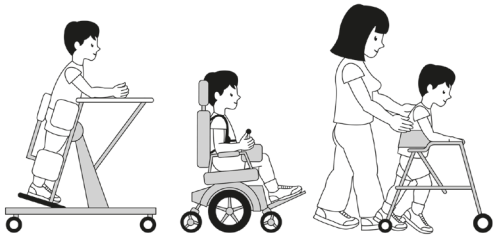
GMFCS Level I
Children walk at home, school, outdoors and in the community. They can climb stairs without the use of a railing. Children perform gross motor skills such as running and jumping, but speed, balance and coordination are limited.



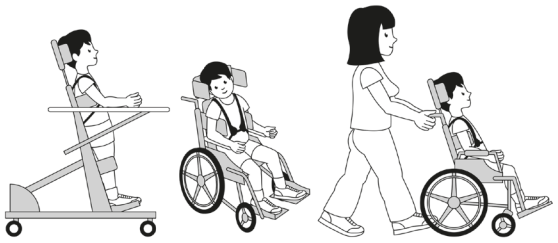
GMFCS Level II
Children walk in most settings and climb stairs holding onto a railing. They may experience difficulty walking long distances and balancing on uneven terrain, inclines, in crowded areas or confined spaces. Children may walk with physical assistance, a hand-held mobility device or used wheeled mobility over long distances. Children have only minimal ability to perform gross motor skills such as running and jumping.



GMFCS Level III
Children walk using a hand-held mobility device in most indoor settings. They may climb stairs holding onto a railing with supervision or assistance. Children use wheeled mobility when traveling long distances and may self-propel for shorter distances.



GMFCS Level IV
Children use methods of mobility that require physical assistance or powered mobility in most settings. They may walk for short distances at home with physical assistance or use powered mobility or a body support walker when positioned. At school, outdoors and in the community children are transported in a manual wheelchair or use powered mobility.



GMFCS Level V
Children are transported in a manual wheelchair in all settings. Children are limited in their ability to maintain antigravity head and trunk postures and control leg and arm movements.

Fig. 77.1 The Gross Motor Function Classification System.

Table 77.2 The Gross Motor Function Classification System

GMFCS level	General descriptor
1	Walks without limitations
2	Catch walks with limitations
3	Walks using a hand-held mobility device
4	Self-mobility with limitations; may use powered mobility
5	Transported in a manual wheelchair

Tizanidine is a central α_2-adrenergic agonist. It is commonly used for spasticity in MS, stroke, and spinal cord injury. It is short-acting, with peak effects 1–2 h after administration; it wears off by 3–6 h. As a result, it is generally reserved for particular activities and times when relief of spasticity is most important. Its pharmacokinetics differ between different preparations and also when taken with/without food, being better when taken under fasting conditions (>3 h after food). As with other agents, its dose can be gradually increased over several days, and withdrawal should be similarly gradual.

Diazepam acts via the GABAA receptors to increase the postsynaptic inhibition of α-motor neurons, treating spasticity and muscle spasms. It is most useful in patients with complete spinal cord injuries. Doses should be increased or decreased incrementally. When used for more than one week, problems with drug-dependency can occur. Its side effects include weakness, sedation, and poor stamina. Abruptly stopping may cause depression, seizures, and an acute withdrawal syndrome.

Botulinum toxin A therapy (Criswell et al., 2006; Steinbok, 2006; Love et al., 2010; Quality Standards Subcommittee of the American Academy of Neurology et al., 2010; Williams et al., 2012; Novak et al., 2013; Cusick et al., 2015) is a neurotoxin, that permanently binds to the presynaptic terminal at the neuromuscular junction causing inhibition of acetylcholine release, functionally denervating the treated muscle. Administration is via direct injection, often with ultrasound guidance to improve accuracy and duration of effect. The effects are seen within 3–7 days and it lasts up to 16 weeks; wearing off as new neuromuscular junctions grow from sprouting nerve rootlets. If used too frequently, it can become less effective due to antibody formation. Care must be taken over the dose; the benefits can be limited if too little is used, but overdose can also occur, leading to systemic effects and widespread muscle paresis. It is licensed for use in upper limb spasticity in adults, bladder instability & overactive bladder, and cervical dystonia. It is widely used for upper and lower limb spasticity in children but is unlicensed for these purposes. It is best used in combination with stretching, serial casting, muscle re-education and strengthening, and orthotic adjustments.

Surgical procedures for spasticity

Several surgical strategies are employed to help combat the adverse effects of spasticity. These involve several different disciplines. Neurosurgical techniques include intrathecal baclofen (ITB), selective dorsal rhizotomy (SDR), percutaneous radiofrequency foraminal rhizotomy, and myelotomy. In addition to these, selective peripheral neurotomy (SPN) is offered by plastic surgeons. Orthopaedic surgery also has a major role to play due to the complex bone and joint abnormalities that can develop due to the spasticity. Constraints of space limit us to a focus on ITB, SDR, peripheral neurotomy, and an outline of orthopaedic surgery.

Intrathecal baclofen

ITB therapy is a well-established treatment for adults and children to treat both spasticity and dystonia. It was reported by Penn and Kroin in 1985 (Penn and Kroin, 1985). They postulated and then proved that direct administration of baclofen into the spinal CSF would achieve the same benefits of oral baclofen with fewer side effects due to direct administration and smaller dosage. This is because the $GABA_B$ receptors in the spinal cord are in the surface layers, allowing the baclofen to work directly. However, in the brain, the $GABA_B$ receptors are in the deeper layers, meaning there are fewer unwanted central effects.

When considering ITB therapy, a test dose is normally performed first (Albright and Ferson, 2006; Delhaas et al., 2008; Phillips et al., 2015). This is done under general or local anaesthetic, with either direct injection of 50–100 μg of baclofen via lumbar puncture, or insertion of a lumbar catheter to allow serial test doses or a test-infusion to be undertaken. The aims of the test dose are to assess the benefits of the treatment and to examine for possible side effects. Patients with dystonia, however, may not experience much benefit from the brief test dose because they tend to get more benefit from the sustained effects of prolonged infusion.

ITB therapy is delivered via an externally-adjustable programmable pump system, which contains a drug reservoir (10–40 ml), a battery, and the drug delivery mechanism. For the surgery, the patient is placed in the lateral position, right-side-up. The pump is implanted in a pocket in the right anterior abdominal wall. Left-sided ITB implants are avoided as gastrostomies are usually inserted on this side. The pump pocket is either subcutaneous, (superficial to the rectus fascia), or subfascial, (deep to the fascia of the rectus and external oblique muscles). The subfascial pocket is particularly useful for smaller, thinner children (Vender et al., 2006; Motta et al., 2007; Fjelstad et al., 2009; Ammar et al., 2012; Motta and Antonello, 2014). Once the pocket has been made, a small incision is made in the lumbar region and the intrathecal catheter is inserted via a lumbar puncture with a Toohey needle. There is debate in the literature about the catheter tip position with authors divided over whether a higher tip position is required for upper limb spasticity/dystonia or not (Grabb et al., 1999; Albright and Ferson, 2006; Dziurzynski et al., 2006; McCall and MacDonald, 2006; Motta et al., 2007; Brennan and Whittle, 2008; Sivakumar et al., 2010; Ughratdar et al., 2012; Varhabhatla and Zuo, 2012). Some studies have suggested that CSF

pulsatile flow is less in the thoracic and lumbar spine, with a consequent reduction in baclofen diffusion for catheters placed in this location (Bernards, 2006; Heetla et al., 2014). The tip position can be guided with X-ray imaging during surgery. In some cases, catheters may be inserted into the ventricle to allow intraventricular baclofen infusion (Albright, 2011; Rocque and Albright, 2011; Bollo et al., 2012; Turner et al., 2012). Once the catheter is inserted to the desired position, the catheter is tunnelled through to the abdominal pocket, secured to the pump and the system is then implanted (Fig. 77.2).

After implantation, the pump is activated and the system can start delivering baclofen immediately. The dose is gradually titrated upwards, usually with increments of 10% every 1–2 weeks. The ITB dose regime can be tailored with flexible dose programming delivering different amounts of baclofen at different times of the day. The pump reservoir needs to be emptied and refilled every 2–6 months depending on the infusion rate and the drug concentration. The system will also need surgery to replace the pump when the battery is nearing end of life.

Risks and unwanted effects of ITB therapy include the risks of the surgery itself, and risks associated with pump system failure of problems with the refill procedures (Albright and Ferson, 2006; Vender et al., 2006; Motta et al., 2007; Protopapas et al., 2007; Brennan and Whittle, 2008; Fjelstad et al., 2009; Heetla et al., 2014; Motta and Antonello, 2014).

- *Drug underdose/acute withdrawal*: Like any mechanical device, an ITB pump can fail, leading to acute baclofen withdrawal syndrome—a life-threatening condition resulting in severe rebound spasticity, rhabdomyolysis, renal failure, and death. This can also occur if the wrong drug concentration is used when refilling the system.
- *Drug overdose* can occur due to errors in programming or pump refilling. When refilling the pump, it is vital to ensure that the needle is inserted into the pump itself and has not skimmed alongside the pump, allowing the refill to be delivered to the pump pocket (a pocket-fill) rather than the pump. A pocket-fill is a life-threatening situation that requires immediate aspiration of drug from the pocket and may require supportive ventilation on intensive care unit (ICU) for the patient until the baclofen wears off.

(B) The lumbar catheter is inserted via a mid-lumbar lumbar puncture. (C) The catheter is connected to the pump. (D) The pump inserted with the catheter coiled behind.

Selective dorsal rhizotomy (SDR)

SDR is a technique for permanently reducing/removing abnormal tone in the legs. It is predominantly indicated for children rather than adults. It involves dissecting and transecting a portion of the lumbar sensory nerve roots to disrupt the abnormal reflex feedback loop. The procedure is done for cerebral palsy, where the brain injury is stable and not progressive. If SDR is performed for a progressive neurodegenerative condition, the benefits will be short-lived. It is also best performed when the only motor disorder is spasticity—if dystonia is present it will usually worsen after SDR.

The first descriptions of dorsal rhizotomy were in 1898, with Sherrington's experiments in a cat model of cerebral palsy (Sherrington, 1898). Foerster then reported the first human subjects in 1913 (Foerster, 1913). However, these two series involved complete transection of lumbar sensory roots, causing numbness and proprioceptive deficits, and hence increased mobility difficulty. Gros (Gros et al., 1967) and then Fasano (Fasano et al., 1978) investigated this further, before Peacock (Peacock and Eastman, 1981; Peacock and Arens, 1982) heralded the modern era of selective dorsal partial rhizotomy, using neurophysiology to select the most abnormal roots prior to sectioning them. The major developments since then were clarification of patient selection criteria (Peacock et al., 1987) and refining the surgery to a two-level laminectomy (Park et al., 1993), then single-level laminectomy at L1 (Park and Johnston, 2006).

Careful MDT assessment is required when considering SDR. The typical patient for SDR is a child with confirmed cerebral palsy, and dynamic spasticity predominantly affecting the legs that interferes with their mobility. They are usually GMFCS level 2–3, mobile with aids, and need adequate strength in their core muscles and leg muscles.

SDR is not usually recommended for patients with dystonia, and those with significant upper limb involvement. Its role for the more disabled GMFCS 4–5 group is under debate.

The surgery is performed via an L1 laminectomy over the conus. The L1–S1 dorsal (sensory) roots are separated from the motor roots. Each root is divided into three rootlets, tested with intraoperative neurophysiology to find the most abnormally active rootlets and then two out of every three rootlets are divided (**Fig. 77.3**). Therefore, approximately two-thirds of each sensory root is divided from L1 to S1. Anal sphincter monitoring is commonly used to help reduce risk of incontinence.

Once the spasticity is removed/reduced by SDR, the underlying muscle weakness is revealed. This requires intensive physiotherapy to build strength. After SDR, patients require 3 weeks' intensive daily physiotherapy, prior to discharge. After this, ongoing regular community physiotherapy is required and patients are encouraged to remain active.

Risks and unwanted effects of SDR include the standard risks of any neurosurgical intradural spinal procedure, and of course this includes risks of paralysis, numbness, and incontinence. However, the use of intraoperative neurophysiology helps reduce this risk to a minimum (Hays et al., 1998; Mittal et al., 2001; Steinbok et al., 2009; Turner, 2009; Fukuhara et al., 2011).

SDR outcomes have been widely studied and reported in the literature, confirming long-term benefits from this procedure both for spasticity control and also reducing rates of orthopaedic surgery requirement too (Bolster et al., 2013; Dudley et al., 2013; Hurvitz et al., 2013; Langerak et al., 2013; Steinbok, 2013; Tedroff et al., 2014; Josenby et al., 2015; Steinbok, 2015; Vermeulen and Becher, 2015). The percentage of rootlets cut in SDR is linked to the degree of

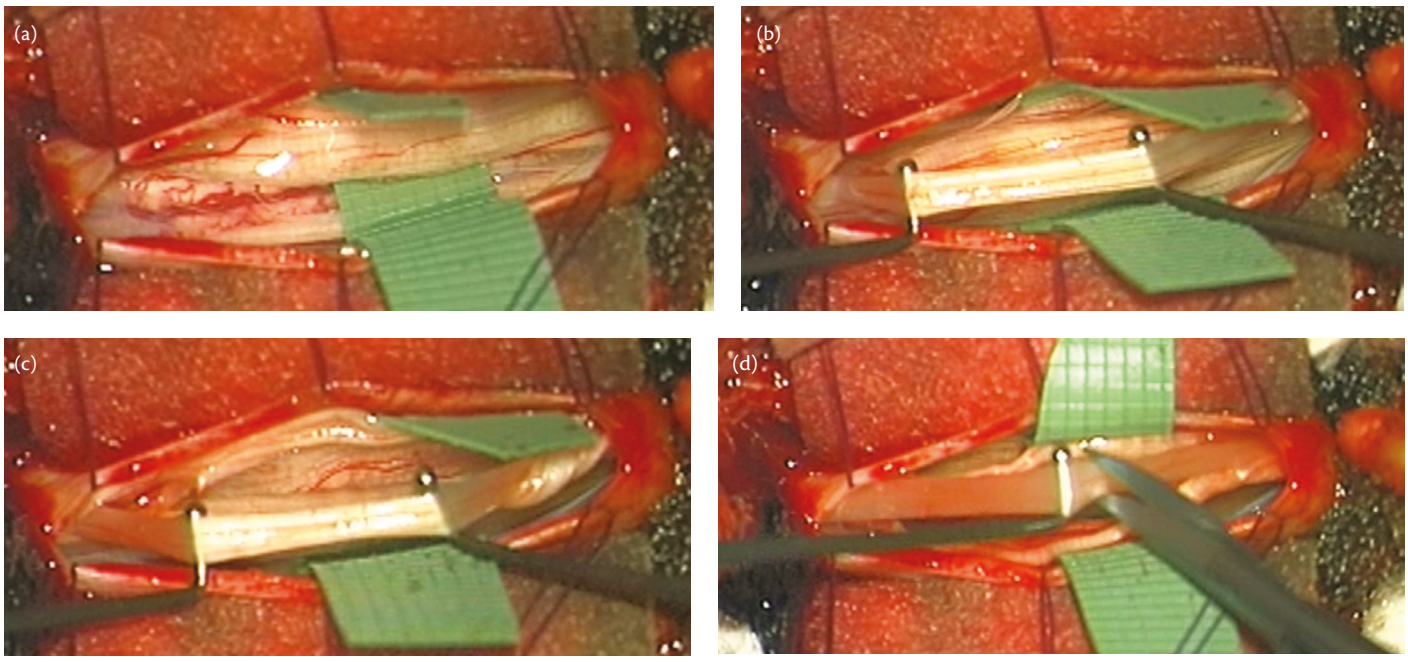

Fig. 77.3 Intraoperative photographs to illustrate the technique of selective dorsal rhizotomy via a single-level laminectomy over the conus. (A) The right-sided dorsal roots of L2-S1 have been separated from the ventral roots and placed into a green silastic sling. (B) The first rootlet of L2 is tested with bipolar stimulation via custom-made nerve hooks. (C) The second rootlet of L2 is tested. (D) The rootlet delivering the most abnormal response is divided.

spasticity control, with less than 50% rootlet section associated with increased return of spasticity.

Upper limb spasticity and selective peripheral neurotomy (SPN)

Upper limb spasticity is characterized by a combination of spastic and flaccid paralysis. Typically, there is spasticity of the flexor pronator muscles combined with flaccidity of the opposite extensor supinator muscles. This results in an adducted, internally rotated shoulder, a flexed elbow, a pronated forearm, a flexed and ulnarly deviated wrist, and a clasped hand with a thumb-in-palm deformity. The flexor pronator tonicity increases with passive stretch and is constant, except during sleep or under anaesthesia. The hypertonic muscles cocontract when the antagonists are used affecting the grasp and release ability.

MDT management aims to maintain function and range of movement. Non-operative measures of physiotherapy, splinting, tone reducing medication, and botulinum toxin should be used fully before considering surgical intervention. The surgical options include rebalancing (tendon transfers), contracture release (myofascial release, musculotendinous lengthening, joint releases), joint stabilizing procedures, and tone reducing procedures, otherwise known as SPN or selective denervation (Zancolli, 2003). SPN is only used in cases where excessive hypertonia is impeding function.

Botulinum toxin treatment mimics the potential effects of SPN on selected nerves and should be used as a preliminary treatment before considering SPN. Local anaesthetic blocks in the outpatient setting can also be used to assess the outcome of potential neurotomy.

SPN can be used in isolation or in combination with tendon transfers, releasing and stabilizing procedures. The surgery involves sectioning of both afferent and efferent pathways of the stretch reflex at the level of the neuromuscular junction. The afferent pathway, corresponding to proprioception of the muscle concerned, is lost and sectioning of the efferent pathway induces paralysis. The aim is to reduce excessive hypertonicity without suppressing useful muscular tone or impairing residual motor and sensory functions. Neurotomy should never involve a mixed nerve trunk of sensory and motor fibres as this can cause deafferentation pain. The responsible motor branches are isolated using intraoperative nerve stimulation together with the operating microscope for visualization. Variable portions (50–80%) of the isolated motor branches are resected and cauterized to prevent regrowth of fibres. The extent of partial section is dependent upon the response to electrical stimulation (Sindou et al., 2007).

SPN outcome depends upon accurately identifying the hypertonic muscles preoperatively and precisely partially denervating these muscles. Recurrence of spasticity can occur when the amount of sectioning is insufficient, however the operation can be repeated.

Orthopaedic procedures

Spastic cerebral palsy is one of the commonest conditions seen in children's orthopaedic practice.

Initially the muscles are functionally short because of spasm or contraction but with time the muscle/tendon unit becomes structurally short from contracture. This also happens to joints—after prolonged movement restriction the joint capsule becomes contracted resulting in abnormal, usually dysfunctional, postures such as fixed knee flexion. Joint instability culminating in dislocation is relatively common in children with spastic cerebral palsy, for instance grossly overpronated (flat) feet and hip subluxation and dislocation (Ounpuu et al., 2002; Pirpiris et al., 2003; Soo et al., 2006; Ross and Engsberg, 2007; Robin et al., 2009; Shore et al., 2012; Silva et al., 2012).

Antispasticity management and physiotherapy are well-established treatments during the precontracture phase but once contractures have developed orthopaedic surgery is needed to restore more normal anatomy and, hopefully, function. There are two main groups of children: those who can walk and those who cannot. The management of the latter group concentrates on prevention of hip dislocation, maintaining feet in a position to wear shoes comfortably and maintaining a comfortable seating position. The management of the former is to maintain or restore standing and walking function.

The role of orthopaedic surgery in walking children has changed following more widespread availability of SDR in the United Kingdom currently offered to those walkers with a GMFCS score of 2–3. Formerly multilevel soft tissue releases (MLSTR) was the mainstay of treatment in walking children when function was plateauing or declining as they grew taller and heavier (Gough et al., 2004; Graham et al., 2005; Khan, 2007; Gorton et al., 2009; Akerstedt et al., 2010; Harvey et al., 2012). This would be for both contraction and contracture. Typically, the child would present with a crouch or jumper's gait (hips adducted, hips and knees flexed, ankles in calcaneus or equinus), which is an energy-sapping way to stand and walk.

Children would undergo orthopaedic surgery between the ages of about 7 and 13 years but management is highly individualized. Typically, hip flexors (sartorius and psoas), knee flexors (gracilis, semitendinosus, semimembranosus medially, and sometimes biceps femoris laterally), and ankle plantarflexors (gastrocnemius or Achilles tendon) are lengthened in one session. Minimal splintage (usually a lightweight below-knee cast for four weeks) is used and early intensive rehabilitation is fundamental.

Children should be assessed in a multidisciplinary clinic and if SDR is done first the child has a further orthopaedic assessment afterwards. Often some areas of tightness will have improved so that any further orthopaedic surgery is less than would otherwise have been the case. The optimal timing of staged orthopaedic surgery is not defined except to say that if further surgery is required if it is best performed within a few months of SDR to facilitate rehabilitation.

Although there is little written, selective percutaneous myofascial lengthening ('percs') is popular method of MLSTR in the United States having advantages of smaller skin incisions and more rapid rehabilitation as well as causing less muscle scarring.

Controversy

At present, the main source of controversy in spasticity management concerns the role of SDR for children with spasticity. Concern has

been voiced because it is irreversible and can make function worse. Rigorous patient selection is therefore key.

Today, most authors accept the role of SDR for children with moderate levels of disability (GMFCS levels 2 and 3)—for whom it can improve function and mobility. Even for this group, there remains controversy. The main critique of the SDR literature is that studies are usually single-centre, small volume, and not case-controlled. This surgery is low-volume and highly specialist which makes larger, case-control studies a challenge. Some authors also cite a lack of long-term outcome data, despite there being an increasing number of reports of up to 26-year follow-up (Langerak et al., 2011; Bolster et al., 2013; Dudley et al., 2013; Hurvitz et al., 2013; Langerak et al., 2013; Steinbok, 2013; Tedroff et al., 2014; Josenby et al., 2015; Steinbok, 2015; Vermeulen and Becher, 2015). Others cite a supposed high risk of paralysis or incontinence, which has not been proven in the literature.

However, some also advocate SDR for more disabled and even wheelchair-bound children (GMFCS levels 4 and 5) as a replacement for ITB therapy (Gump et al., 2013; Ailon et al., 2015; Steinbok, 2015; Vermeulen and Becher, 2015). For this group, the indications and goals of treatment are different because these children will often not achieve independent walking. They are also more likely to have mixed spasticity and dystonia, which can make the outcome less certain. Some advocate offering SDR instead of ITB for GMFCS level 4–5 children to help with personal hygiene and ease of movement, because SDR means that they will not require the regular hospital reviews and pump refills/replacements over the subsequent years. This has not been proven to be the case, however, and is certainly an area for future clinical trial research. For this group SDR can also remove/reduce their ability to stand for transfers with associated negative consequences for quality of life.

In addition, there is interest in whether SDR could have a role in genetic conditions (Kai et al., 2014), acquired injuries (Langerak et al., 2014; Reynolds et al., 2014) (e.g. spinal trauma or postinfectious), as well as patients with hemiplegia (Oki et al., 2010; Gump et al., 2013).

Conclusions

Spasticity treatment requires carefully planned multidisciplinary assessment and treatment. Treatment strategies should be tailored around the patient's functional and physical needs, with input from allied health professionals with rehabilitation, medical, and surgical disciplines. Regular reviews are required as part of this to ensure that treatments remain suited to the individual. The treatment goals include improving tone, alleviating spasms, controlling gastrointestinal effects, and controlling bladder function, with the aim of protecting function and minimizing the deleterious effects of spasticity and their condition as a whole.

Pain pathophysiology and surgical management

Richard Mannion and Rokas Tamosauskas

Pain pathways—anatomy and physiology

Transduction and transmission of sensory input from our environment to the brain starts first in primary sensory neurons (first order neurons). This group are anatomically and functionally heterogenous, their cell bodies located in the dorsal root and trigeminal ganglia and their axons divided into a peripheral projection towards their innervation targets and a central projection into the spinal cord (**Fig. 78.1**).

Primary sensory neurons can be divided into the following: large myelinated Aβ fibre afferents responsible for conveying low-threshold mechanical sensation and vibration; thinly myelinated fibre Aδ afferents, with smaller cell bodies responsible for fast pain (e.g. pinprick); and small, unmyelinated C-fibre afferents involved in pain and temperature sensation. All these cells have peripheral terminals spread widely throughout their innervation tissue as 'free nerve endings', and transduction through highly evolved, complex processes allows the preferential detection of peripheral stimuli that is strictly regulated. Nociceptors are anatomically, functionally, and neurochemically distinct, and respond to certain stimuli through specific receptor-mediated mechanisms (Woolf and Ma, 2007). This results in predictable stimulus-response relationship within primary sensory neurons that allows reliable and reproducible coding of sensory stimuli from our environment to the brain. It is important to note, however, that these relationships are not 'hard wired'; they are continuously and actively maintained in the physiological state, and can therefore be altered in disease states, whereby primary sensory neurons can change phenotype and consequently their function in relation to coding for peripheral stimuli, that is, transduction and transmission. Indeed, they can even start to fire spontaneously in the absence of a peripheral stimulus—one of the recognized mechanisms of spontaneous (i.e. stimulus-independent) neuropathic pain (Costigan et al., 2009).

Pain transduction and transmission

In the physiological state, the sensation of physical pain results from the detection of peripheral stimuli causing potential or actual tissue damage: this is nociception. Nociceptors, that is, primary sensory neurons with the capacity to detect noxious stimuli (e.g. heat, chemical, mechanical) are the small, unmyelinated afferent fibres, with cell bodies in the dorsal root ganglia, that innervate peripheral structures such as skin, muscles, and viscera (Woller et al., 2017). Their central axons run within the dorsal root to the dorsal root entry zone where they enter Lissauer's tract in the dorsolateral white matter funiculus of the spinal cord.

As well as the usual neurotransmitters such as glutamate, nociceptors preferentially express several peptides that play a role in neurochemical transmission, such as substance P and calcitonin gene-related peptide (CGRP). Following their discovery, early excitement that these could present new therapeutic targets for pain management have not been realized, as the roles of peptide transmitters are complex, but they do play an important role in sensory transmission and have a distinct and longer lasting action on postsynaptic neurons in the dorsal horn, that works in conjunction with fast transmitters such as glutamate. In addition, these peptides can be found in the peripheral terminals of nociceptors, and anterograde action potentials from the cell body to these terminals leads to the release of peptides, that results in vasodilation, plasma extravasation and recruitment of immune cells, producing neurogenic inflammation.

Most are polymodal (i.e. they can detect more than one type of stimulus modality). Typically they have a higher activation threshold for detection of mechanical stimuli than Aβ fibres (though this nociceptive threshold may vary between tissues, e.g. cornea vs. skin). A large number of mechanically sensitive proteins including mechano-gated ion channels have been identified across different functions and species (Delmas et al., 2011; Delmas and Coste, 2013).

Thermosensitivity is thought to be mediated via a family of receptor proteins called TRPs (transient receptor proteins; Mickle et al., 2015). The TRPV1 receptor is expressed by approximately 40% of primary sensory neurons, many of which are small unmyelinated C-fibre neurons, and the ion channel opens in a temperature-sensitive manner. TRPV1 is thought to be involved in heat detection, and interestingly altered TRPV1 expression in sensory neurons has been observed experimentally in different disease models. There are several other related proteins that have been implicated cold

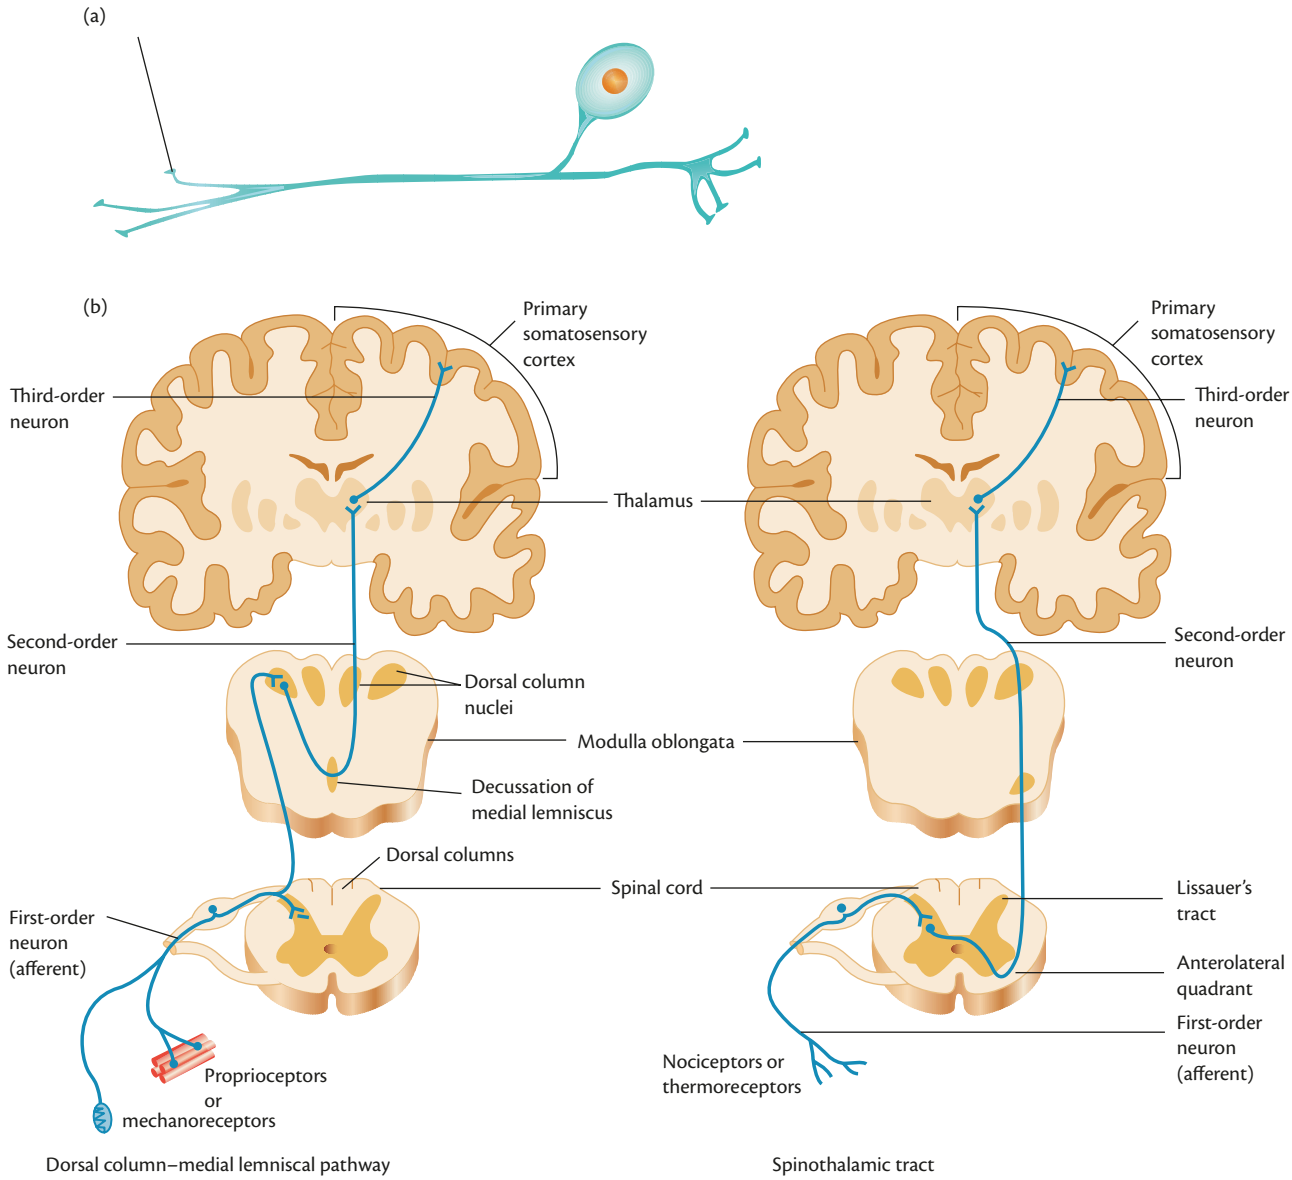

Fig. 78.1 (A) Primary sensory neurons have a single axon that leaves the cell body and divides into a long peripheral axon and a shorter centrally projecting one. (B) Cartoon showing major sensory pathways.

detection, innocuous warm detection, and noxious heat sensation in normal and diseased states (Fig. 78.2).

Different voltage gated ion channels are preferentially expressed by nociceptors versus non-nociceptive primary sensory neurons, the best characterized of which are the Na_V ion channels (1.7, 1.8, 1.9). These channels are critical to normal sensory transduction and transmission in nociceptors, and certain mutations in the genes coding for these channels are known to cause inherited chronic pain states (Cummins et al., 2007). Of note, sodium channel function changes in chronic pain states such as inflammation and following nerve injury, such that receptors are sensitized (Liu and Wood, 2011). Other ion channels implicated in nociception are the acid-sensitive ion channels, also preferentially expressed by nociceptor neurons (Dubé et al., 2009). These ion channels open at low pH, which are the conditions found in inflamed tissue where nociceptors are more sensitive and are activated at lower thresholds (Fig. 78.3).

There is a subpopulation of nociceptors which remain silent in the physiological state, not responding to any peripheral stimuli, even noxious ones, but are activated following tissue or nerve injury, when they begin to respond to mechanical and thermal stimuli. These neurons may play a role in altered pain responses during disease states such as inflammation (see Fig. 78.4).

Primary relay—the dorsal horn

Once a nociceptor is activated, action potentials pass along the axon and through the dorsal root ganglion (or trigeminal ganglion) to access the spinal cord. At the spinal levels, these fibres pass though the dorsal roots to the dorsal root entry zone (DREZ). Here, there is anatomical separation of large myelinated A-fibre axons and small, unmyelinated C fibres. A-fibre central axons pass into the ipsilateral dorsal columns to run rostrally. As they enter the white matter of the spinal cord from the DREZ, they provide a collateral axon that enters

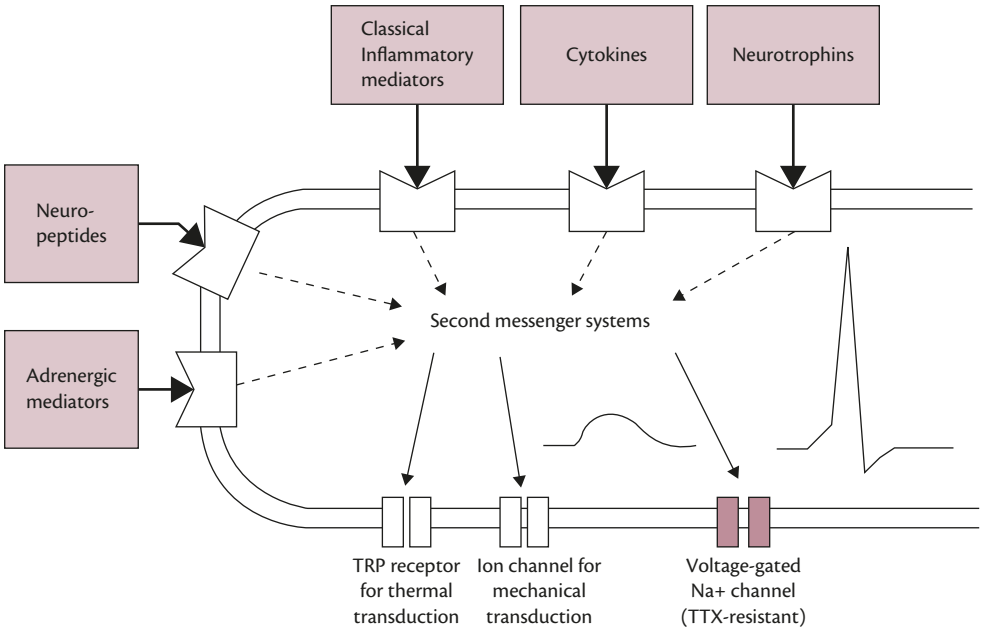

Fig. 78.2 Immunohistological TTX–resistant sodium channel expression in the dorsal root ganglion, demonstrated with immunohistochemical staining against peripherin, a protein found in larger A-fibre afferents. Note the positive cell bodies are largely the small nociceptor neurons.

the grey matter of the dorsal horn of the spinal cord. This axon plays a key role in sensory gating.

C fibres enter the DREZ and either pass through, to access the dorsal horn, or run a few segments rostrally or caudally in Lissauer's tract, prior to termination in the dorsal horn. These fibres are known to enter and terminate in the superficial laminae of the dorsal horn, also known as the substantia gelatinosa. Here they synapse onto the dendrites of neurons whose cell bodies lie within the dorsal horn. The majority of these cells are local interneurons involved in local anterograde and retrograde relay circuits. Some are excitatory neurons while others are inhibitory. Therefore, the superficial laminae of the dorsal horn contain a wide range of excitatory and inhibitory neurotransmitters and neuropeptide transmitters that forms a complex gating system, controlling how information is relayed from our environment (internal and external) to the brain. In addition, there are some neurons with cell bodies found in superficial dorsal horn and the deeper dorsal horn layers, that themselves have a projecting axon which crosses the spinal cord segmentally, anterior to the central canal to run in the spinothalamic tract (STT) tract (see Box 78.1).

Wide dynamic range (WDR) cells

These neurons with cell bodies located in the dorsal horn of the spinal cord, predominantly the deeper laminae, receive and respond to input from Aβ fibres, Aδ fibres and C fibres. They can respond in a graded fashion to innocuous and noxious stimuli. They are also known to have large receptive fields, whereas cells in the superficial laminae have much smaller receptive fields. It is thought that localization of a noxious stimulus is therefore encoded by populations or networks of neurons.

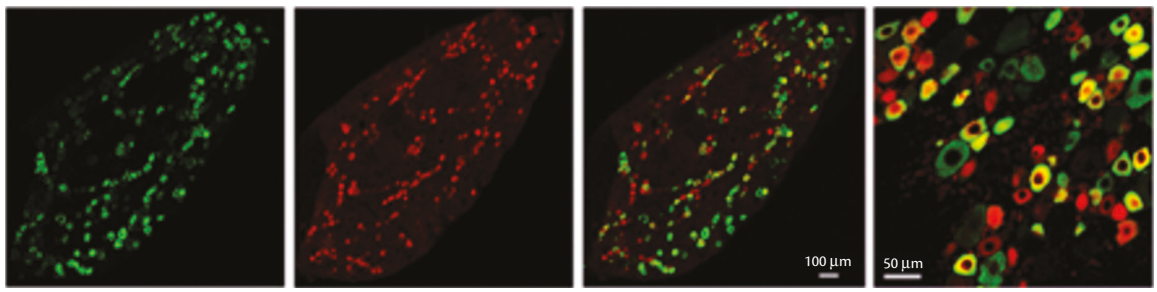

Fig. 78.3 Original model proposed by Melzack and Wall (1965). L–large/S–small sensory neurons. T–Transmission neurons. By exciting SG (substantia gelatinosa) neurons, this allow presynaptic modulation of sensory input to projection neurons via excitatory and inhibitory mechanisms, with further control superimposed from descending pathways

Box 78.1 Gate theory

'The Gate Theory of Pain', published by Melzack and Wall in *Science* in 1965, provided a mechanism to explain how nociceptive input could be coded by the sensory system at the first sensory relay in the dorsal horn of the spinal cord. It focused on recently discovered mechanisms of presynaptic control of synaptic transmission from large and small sensory neurons, which was proposed to 'gate' incoming information, depending on the balance between these inputs (see Mendell (2014) for full review). It also incorporated other mechanisms, such as descending control pathways from the brain and the convergence of nociceptive and non-nociceptive input onto the same neurons in the spinal cord, involved in transmission to the brain. While it was later found that not all the predictions were accurate, the Gate Theory provided a catalyst for further research and understanding within the burgeoning field of pain neurobiology. It helped to change the accepted view of pain mechanisms, with a move away from fixed 'labelled line' pain pathways to the realization of both adaptive and maladaptive processes mediating physiological and pathological pain states. See Figure 78.4.

While there are complex neural arrangements involving finely balanced processes of excitatory and inhibitory transmission through anterograde projection and retrograde feedback, in the physiological state at baseline, a fixed peripheral stimulus will typically produce a predictable response. However, our experience of pain when presented with a noxious stimulus can be highly varied. It was recognized long before we developed an understanding pain anatomy and physiology that our experience of pain very much depended on circumstances (i.e. pain perception was contextual). Henry Beecher recognized in 1956 that soldiers could suffer extensive battlefield injuries yet require little or no analgesia, whereas similar injuries in civilian casualties produced much more pain (Beecher, 1956). Much of the modulation is now known to occur within the dorsal horn of the spinal cord, the first sensory relay.

Spinal gating—modulation of C-fibre input

Through mono- and poly-synaptic pathways in the dorsal horn, there is convergence of primary sensory input on to projection neurons. This allows different inputs to modulate transmission of others. Therefore, non-nociceptive inputs can inhibit nociceptive input and the appreciation of pain; for example, rubbing an injured area reduced the perception of pain. Attempts to explain observations like this led to publication of the gate control theory by Melzack and Wall in 1965 (see **Box 78.1**).

There are several different mechanisms within the spinal cord by which sensory transmission to the brain is modulated, either increased or decreased, involving local excitatory and inhibitory interneurons, and descending pathways from the brain. Direct electrical stimulation of the periaqueductal grey (PAG) produces a profound analgesia that is opioid-mediated. The PAG projects to the rostroventral medulla (RVM), with includes the raphe nuclei of the medulla, rich in serotonin. In turn, this region projects to the dorsal horn of the spinal cord where they also influence transmission from primary sensory neurons to the central nervous system. These spino-bulbo-spinal pathways are thought to form a critical loop in 'regulating the gain' in sensory processing within the primary relay. It has been suggested that one mechanism by which acupuncture may impart analgesia may be through the activation of descending pathways, a phenomenon known as diffuse noxious inhibitory control (DNIC). Further, these modulatory mechanisms are not fixed; nerve or tissue injury can alter the interplay and impact on how sensory information is relayed to the brain (D'Mello and Dickenson, 2008).

Ascending pathways

Dorsal horn projection neurons are responsible for relaying sensory information from nociceptors to the brain. This happens via a number of pathways. Some are responsible for projection to thalamus and subsequently neocortex, thought to be critical in producing a conscious response to noxious stimuli. Others are responsible for producing more complex behaviours such as avoidance (away from the noxious stimulus), autonomic responses (e.g. sympathetic activation) and emotional aspects (e.g. fear, anger, sadness). Therefore, as sensory information passes from primary sensory neurons to higher centres, there is divergence of inputs to different targets. This brings new levels of complexity to the organization of the sensory system, which hampers our understanding of the significance of each component (relative to another), and makes the process much more difficult to study scientifically. Interestingly, none of the 'pain pathways' described next are specific to noxious input; all contain cells that respond the low-threshold input, noxious input and 'wide dynamic range'.

The spinothalamic tract (STT)

This has been loosely named the ascending 'pain pathway' of the spinal cord, but this is an oversimplification. The STT runs contralaterally in the ventral and ventrolateral white matter funiculi. It has two components, lateral and ventral (anterior). The lateral STT is more heavily implicated in pain and temperature sensation, while the ventral STT is implicated in crude touch and firm pressure sensation. The STT is organized somatotopically; in the cervical spinal cord, cervical fibres are most medial and lumbosacral fibres lateral. The primary target is the ventroposterolateral (VPL) nucleus of the thalamus, part of the thalamocortical sensory coding system.

Spinoreticular tract (SRT)

This pathway also consists of axons projecting from dorsal horn projection neurons in lamina V but also deeper laminae extending into ventral horn (VII, VIII) and medial grey matter (X). Like the STT, the SRT is also located in the ventral quadrant of the spinal cord white matter, close to the lateral STT, and it projects to a number of targets including reticular formation (located in the midbrain, pons, and medulla), thalamus (lateral and dorsal reticular nuclei) and the nucleus reticularis gigantocellularis, as well as others targets.

Spinomesencephalic tract

This pathway is located ventral to the lateral STT, with projection neutron cell bodies located in superficial (I) and deep laminae of dorsal (IV, V) and ventral (VII, VIII) horns. It projects to the parabrachial nuclei and PAG; note that this region has formed a target for deep brain stimulation as a treatment of chronic pain—see next). The parabrachial limb has been implicated in emotional response to noxious stimuli, as the parabrachial region, located at the junction of midbrain and pons, part of the lateral reticular formation, and has onward projections to the amygdala as well as thalamus, hypothalamus. Is thought to contain a 'hedonic hotpot' involved in liking certain stimuli, and in addition to pain receives inputs from the gustatory portion of the solitary nucleus and is implicated in taste.

Pain pathways—pathophysiology

In the physiological state, nociceptors detect the presence of noxious stimuli and alert us to their presence. While pain is generally an unpleasant experience, it is a crucial component of our integrity and survival, by protecting us from harmful stimuli (e.g. a hand on a hot plate leading to a rapid withdrawal response), or limiting the extent of damage (swollen ankle forcing us to limit weight-bearing and allow healing). The absence of nociception leads inevitably to serious and potentially life-threatening harm; rare individuals with congenital insensitivity to physiological pain have lives that feature repetitive injury and early death; other examples are the Charcot joint in diabetic patients, or the well-recognized eye complications that can occur in patients with combined facial and trigeminal palsy.

It is important to recognize that the function in sensory pathways involving primary and secondary sensory projection neurons, interneurons of the spinal cord, brainstem and thalamus, and the descending innervation they receive, are not fixed, like a light-switch, in a passive, predetermined, hard-wired system. The phenotype of any individual neuronal cell, and therefore its function, is actively maintained by the local chemical and electrical environment. Therefore, processes that result in a change to the local neuronal environment can lead to a change in neuronal phenotype that has functional implications for the sensory system as a whole (Woolf and Salter, 2000).

To appreciate this, it is useful to consider two disease states: inflammation, and nerve injury (e.g. from trauma, compression, tumour invasion).

Inflammation

In inflamed tissue, typically non-painful stimuli (e.g. light pressure) become painful (pain hypersensitivity). As just referred to, this example of increased or abnormal pain is likely to be evolutionarily advantageous, by protecting an injured area from further harm and allowing healing. Unfortunately, however, there are many disease states where inflammation can become autonomous and serve no useful purpose (e.g. a rheumatoid joint). Under these circumstances, chronic pain becomes the disease. There is now much greater appreciation of interactions between the nervous system and immune system, resulting in reciprocal modulation of function, in both physiological and disease states (McMahon et al., 2015).

Whatever the trigger—tissue injury or auto-immune processes—inflammation is mediated by vasodilatation, plasma extravasation, tissue swelling, the recruitment of immune cells and the release of inflammatory mediators. Thermo- and chemosensitivity of nociceptors means that a change in the local environment, with an increase in inflammatory cytokines (e.g. IL-1, IL-6, TNFα), elevation in local temperature, and reduction in pH lead to altered activity patterns and increased pain. This is not simply an increase in stimulus resulting in an increased response; inflammatory cytokines can alter the processes of sensory transmission from peripheral tissue to the spinal cord, via post-translational modifications to surface receptors and intracellular signalling proteins, and transcriptional changes within the cell bodies of nociceptors. These changes of protein expression and phenotypic identity lead to an alteration in function, such that the same response results in increased gain and therefore more action potential activation. Wherever one looks at primary sensory neurons—the peripheral terminal, the axonal membrane, the cell body, or the central terminals in the spinal cord—inflammation produces changes in function, largely mediated by protein modification, itself driven by altered chemical environment and/or activity-dependent mechanisms.

The presence of inflammatory cytokines in peripheral tissue has been shown to correlate with increased pain levels and alterations in the relationship between stimulus and response. This results in phenomena such as hyperalgesia (increased pain from a noxious stimulus) and allodynia (pain from an innocuous stimulus). Furthermore, these changes can be long-lasting. Understanding these changes gives us insight into how some of the features of chronic pain states, which typically feature abnormal pain behaviour (unlike 'physiological (nociceptive) pain') may be mediated.

Nerve injury

There are many causes of peripheral nerve injury in addition to trauma or compression (e.g. from a disc prolapse), including systemic diseases causing polyneuropathy, tumour invasion, and inflammation itself. Classical lumbar or cervical radiculopathy is now understood as more than just a compression neuropathy, with the recognition of complex interplays between mechanical compression and an associated inflammatory response. Several inflammatory markers have been identified in neuropathic pain models and clinical studies, which potentially offer new pharmacological treatment targets and further revise the role of surgery for these conditions.

Of course, decompressive surgery remains an important, evidence-based treatment in the management of some patients with spinal cord or radicular compression, particularly patients with bowel or bladder impairment, or evolving neurological deficit.

Unfortunately, most patients with neuropathic pain do not have nerve compression that can be treated surgically, and symptom

Table 78.1 Examples of events observed in primary sensory neurons or their central terminals in disease states, with postulated clinical manifestations

Event	Disease state	Symptom
Peripheral sensitization	Inflammation	Pain hypersensitivity (hyperalgesia, allodynia)
Wallerian degeneration/ demyelination/axonal death	Peripheral nerve injury	Numbness/reduced sensation
Ephaptic transmission	Peripheral nerve injury	Spreading pain (increased receptive fields)
Ectopic activation—C fibres	Inflammation, nerve injury	Spontaneous burning pain (stimulus-independent)
Cell death—primary sensory neuron	Peripheral nerve injury	Numbness/reduced sensation
Cell death—dorsal horn interneurons (inhibitory)	Peripheral nerve injury	Spontaneous pain, spreading pain (increased receptive fields)
Central sensitization	Inflammation, nerve injury	Pain hypersensitivity (hyperalgesia, allodynia)

control can be extremely challenging, arguably one of the most difficult clinical problems to manage. Further, this is a huge societal problem. These patients classically have a mix of negative (sensory reduction or loss) and positive symptoms (hyperalgesia, allodynia, paraesthesia/dysaesthesia, spontaneous pain, hyperpathia). The effects of peripheral nerve injury on primary sensory neurons are widespread (Costigan et al., 2009), and critically do not confine themselves to the injured neurons, but also involve adjacent, uninjured cells and fibres. Table 78.1 details some of the pathophysiological changes that occur following peripheral nerve injury and their likely clinical manifestations.

Spinal mechanisms of chronic pain: Sensitization and disinhibition

The effects of peripheral inflammation and nerve injury on primary sensory neuron function results in changes in central nervous system sensory processing (D'Mello and Dickenson, 2008). The underlying causes are multifactorial, including activity-dependent mechanisms as well as changes in protein function (transcriptional and post-translational modifications), themselves resulting in changes in cellular activity and behaviour. These changes can be long-lasting, and can drive postsynaptic changes in activity, protein expression, and even cell death dorsal horn neurons. Changes with the spinal cord can be considered under the headings of sensitization and disinhibition.

Following nerve injury and inflammation, chronic pain often extends spatially beyond the usual dermatomal area, resulting in a zone of secondary hyperalgesia, which can become independent of the initial injury. These symptoms cannot be explained by changes in the peripheral nervous system, but instead reflect changes in spinal and supraspinal networks. Nociceptive mechanisms, whereby only physiological high-threshold stimuli caused pain, can change such that the system now results in pathological low-threshold pain hypersensitivity.

One important mechanism responsible for this change is central sensitization (Latremoliere and Woolf, 2009; see Box 78.2). Other long-lasting consequences of nerve injury include neuronal phenotypic changes due to altered gene transcription and post-translational modification of membrane proteins, and decreasing GABA-ergic and glycinergic tone in the dorsal horn. This 'disinhibition' is mediated by mechanisms such as reduced descending inhibitory control, loss of GABA-ergic or glycinergic interneurons through cell death, reduced GABA or GABA-synthesizing enzyme (e.g. glutamate decarboxylase), and altered properties of GABA receptors, glycinergic receptors, and cation-chloride cotransporters. This further contributes to central hyperexcitability and augmentation of pain pathways.

An emerging role in sensory transmission and pain processing in disease states has been identified for microglial (macrophage-like) cells, within the CNS (McMahon and Malcangio, 2009). Following nerve or tissue injury, there is a rapid morphological and functional change in microglia, which has a profound impact on sensory processing (Calvo and Bennett, 2012). These neuroimmune interactions within the CNS have identified potential targets for development of novel pain management strategies for chronic pain conditions (Scholz and Woolf, 2007).

Thus, changes in phenotype and function of primary sensory neurons, spinal interneurons, and projection neurons, as well as non-neuronal cells, can lead to profound alterations in the functional spinal relay and establishing chronic pain states that can extend well beyond the period of primary tissue injury.

Supraspinal mechanisms

Pathophysiological changes in the sensory system following peripheral tissue or nerve injury are not confined to primary sensory neurons or the spinal cord. Structural changes, changes in excitatory and inhibitory transmitters and in functional connectivity have all been detected in the brains of chronic pain patients. The challenge remains how to relate these changes to the cognitive, sensory, and emotional pain experience, understanding how much of this is cause versus effect, and whether these changes are reversible.

Box 78.2 Central sensitization

Under physiological circumstances, a fixed stimulus results in a predictable response. However, following tissue or nerve injury, where activity in primary nociceptors increases, this can lead to an increased response centrally, to the same stimulus peripherally. This is central sensitization, defined by the International Association for the Study of Pain (IASP) as the 'increased responsiveness of nociceptive neurons in the central nervous system to their normal or subthreshold afferent input'. Activity-dependent mechanisms of central sensitization include homosynaptic long-term potentiation—with exaggeration of nociceptor responsiveness—and heterosynaptic potentiation—recruiting low-threshold Aβ fibre inputs into the pain pathway, and these mechanisms may be driven and sustained by ectopic activity in the injured nerve.

Central sensitization is produced by the activation of several protein kinases by the neurotransmitter glutamate and various neuropeptide transmitters, which lead to post-translational and transcriptional changes in postsynaptic receptors (e.g. the N-methyl-D-aspartate (NMDA) receptor). That central sensitization is a major driver of neuropathic pain is supported by the action of drugs that reduce central excitability, including gabapentinoids (e.g. gabapentin and pregabalin), tricyclic antidepressants (e.g. amitriptyline), SNRIs (e.g. duloxetine), and NMDA antagonists (e.g. ketamine). Central sensitization has become a key focus for the development of new analgesics, and is the rationale behind pre-emptive analgesia (i.e. to prevent increased primary nociceptor input to the CNS).

Surgical procedures for management of chronic pain

There is a long history of ablative surgical procedures for the management of chronic pain (Loeser, 2006), though they predate a modern understanding of pain neurobiology and the likely underlying mechanisms that drive chronic pain. Of course, there is still some way to go before we fully understand these mechanisms and can identify them in individual patients, and even further from being able to offer evidence-based, effective management (von Hehn et al., 2012; Vardeh et al., 2016). Many of the current 'strategies' for managing chronic pain patients is empirically based, and we are currently unable to predict who is likely to respond to different pain interventions (e.g. with pharmacology, injection therapies, acupuncture, physical therapy, TENS, and others) nor explain the reason as to why some do respond, while others do not. Understanding sensory pathophysiology, acknowledging the profound alterations that occur in primary sensory neurons, the spinal cord, and higher centres in many ways questions the rationale for surgical management of chronic pain with, particularly for ablative/irreversible procedures which arguably might cause more maladaptive sensory plasticity than they solve. Perhaps this explains why many of these procedures only result in short-lived improvements in chronic pain, and only then in some patients, and have a recognized incidence of exacerbating neuropathic symptoms. Many of the destructive procedures have fallen from favour in recent years in most neurosurgical centres, and are now often reserved for terminal cancer patients with a short prognosis. It is also important to acknowledge the placebo effect when considering the utility and efficacy of any surgical procedure, particularly when only short term follow up is utilized (see Colagiuri et al. (2015) for review of placebo effect and underlying mechanisms, widely recognized in the field of surgery).

In carefully selected patients and in centres with high expertise, some of these procedures are still practised and considered useful (see Sindou et al., 1990 for review).

DREZ lesions

These were first attempted in the 1970s by Marc Sindou in Lyon and gained popularity thereafter. The procedure is still used, although much less frequently, for central or deafferentation pain syndromes such as brachial plexus injury, phantom limb pain, traumatic spinal cord injury, and cancer pain, as well as spasticity. Sensory axons of different diameters are mixed in the dorsal root, but organize just before they reach the spinal cord. The root divides into rootlets and the small fibres lie laterally, prior to entering Lissauer's tract, while the larger fibres enter more medially, nearer to the dorsal columns.

The procedure is done through a laminectomy or hemilaminotomy. The pia over the DREZ is opened and microsurgical lesions are made, either with the use of diathermy or radiofrequency ablation. Complications include corticospinal tract or dorsal column injury, continence issues, and worsening or persistent neuropathic pain. The procedure is now generally considered only as a last resort for patients who have failed all other less invasive management strategies.

Cordotomy

The lateral spinothalamic tract (STT) carries signals of pain, temperature, and touch from the contralateral side, therefore a destruction or interruption of the tract should lead to the analgesia and loss of sensations to heat and cold on the contralateral side. Open cordotomy was described in 1911, but the procedure was associated with significant morbidity and mortality. The development of percutaneous techniques has made the procedure less invasive and cordotomy is a recognized component of the algorithm for management of malignant unilateral pain. Computed tomography (CT)-guided techniques have allowed more precise needle positioning and lesioning. Endoscopic cordotomy techniques also have been explored.

How does it work?

The lateral STT tract is composed of fibres decussating from the contralateral side of the spinal cord. At each spinal level, a second order neural axons travel on the ipsilateral side of the spinal cord for two to five levels, before decussating to the contralateral anterolateral spinal cord where they join lateral STT. At the C1–2 level, the lateral STT has clear somatotopic organization: the anteromedial part has fibres from the upper extremity, shoulder, anterior chest, whereas posterolateral aspect contains the fibres from lower extremity, lower back, and the pelvis (Fig. 78.5).

Several techniques of percutaneous cordotomy have been described. A radiofrequency (RF) cannula is inserted via the C1–2 foramen into the anterolateral part of the spinal cord under local anaesthesia with either fluoroscopic (classical technique) or CT guidance. The aim is to penetrate the dura and enter the anterolateral spinal cord perpendicular to the sagittal plane, just anterior to the dentate ligament. Sensory stimulation should produce clear change in thermal sensations (heat or cold) with associated tingling on the contralateral side, ideally, but not necessarily overlapping the area of pain. Motor stimulation should produce ipsilateral contractions of the neck and shoulder muscles due to the stimulation of the adjacent corticospinal tract. Thermal sensation changes with stimulation on the contralateral side is considered a reliable predictor of good analgesic effect. Then, a thermal radiofrequency lesion is carried out in an incremental fashion, with continuous monitoring of motor function on the ipsilateral side. After lesioning, there should be a marked difference in sensation to pinprick between the sides.

CT guided anterior transdiscal approach has been described. Some have also advocated laser lesioning with a lateral endoscopic technique, for even better precision and accuracy.

Indications for percutaneous cordotomy

Cooperative patients who suffer unilateral nociceptive pain below C5 due to malignancy, despite appropriate palliative pharmacological and interventional management, with adequate lung function and life expectancy from 6 months to less than 1 year, can be considered for cordotomy. The best-studied groups of patients are those with malignant mesothelioma, Pancoast tumours, and metastatic lung cancer. There is some low-level evidence that cordotomy is not effective for neuropathic pain.

Evidence of efficacy

Most publications are retrospective, with some prospective case series. A recent systematic review looked at percutaneous cordotomy in the treatment of mesothelioma-related pain. In 160 patients, complete or partial pain relief was achieved immediately after the treatment in 94% of cases. Recurrence of pain is widely recognized in patients who live beyond a year.

Complications

In experienced hands with carefully selected patient, major complications are very rare (<1%). Procedure specific complications include transient or permanent motor weakness in the ipsilateral extremity (leg > arm), dysaesthesia, mirror pain in the ipsilateral side, and dyspnoea due to intercostal/diaphragmatic muscle weakness. General complications such as chest infection, orthostatic hypotension, urinary retention, incontinence, sexual dysfunction, confusion, and death have also been described. Lesions affecting nearby anterior spinocerebellar, reticulospinal and corticospinal tracts can produce ataxia, or disturbed autonomic and motor control.

Bilateral cordotomy

This has been used in very small numbers for bilateral cancer pain, or development of a new pain following unilateral cordotomy. There is very scant efficacy data, however, it is known that bilateral cordotomy has a much higher complication rate including ataxia, motor weakness, dysaesthesia, incontinence, respiratory depression, and death.

Practical issues

Following the arrival of long-term oral and transdermal opiate formulations (**Box 78.3**) and intrathecal drug delivery systems, the number of cordotomy procedures has been steadily declining. This is despite the growing number of malignant mesothelioma cases (anticipated to peak around 2020) and often suboptimal pain relief with pharmacological and interventional therapies. While this can be a useful method of pain relief in some patients, it may become extinct as fewer are performed and physicians become more reluctant to offer destructive and irreversible treatments.

Mesencephalic tractotomy

Like thalamotomy, this procedure has been used to treat poststroke pain and cancer pain though not in high numbers and there are few surgeons with experience. Mesencephalotomy is used for patients

Box 78.3 Opiates—kings of pain control?

Opioid receptors are the proteins that control nociceptive, hedonic, emotional, as well as autonomic, neuroendocrine, and immune responses. Gene cloning identified three receptor genes only, encoding mu, delta, and kappa receptors.

Receptor-deficient knock-out mice exhibit enhanced pain sensitivity. In models of acute pain, mu receptors modulate mechanical, chemical, and supraspinally controlled thermal nociception, while kappa receptors modulate spinally mediated thermal nociception and visceral pain. There is strong evidence for a role of delta receptors in reducing hyperalgesia in situations of inflammatory and neuropathic pain.

Endogenous opioid peptides. Met- and leu-enkephalins act on the spinal opioid receptors in lamina I and II of the dorsal horn, spinal trigeminal nucleus and periaqueductal grey (PAG). They are also present in the gastrointestinal (GI) tract and adrenal medulla. Dynorphins have actions on multiple spinal and supraspinal sites, but are considered to be weak analgesics. Multiple complex actions of beta-endorphins are largely limited to the central nervous system sites.

Spinal actions of opioids occur in tetrasynapse composed of the central terminal of primary afferent neurons, projection neurons, astrocytes, and microglia in the spinal cord dorsal horn. Opioids:

1 hyperpolarize primary afferent membrane by closing Ca ++ channels and opening K + channels, thus reducing glutamate release from nociceptive afferents (presynaptic effect); nociceptive input from the periphery is reduced;
2 reduce intracellular Ca ++ and increase K + postsynaptically thus quenching several mechanisms that would otherwise lead to hyperexcitability of second order neurons.

Supraspinal sites of opioid analgesia

There are multiple mechanisms and action sites in the brain. Opioids interact with 5-HT, GABA-ergic, and possibly other systems of central descending regulation. They move rostroventral medial medulla (RVM) output towards descending inhibition. Opioids also play an important role in regulating pain experience.

Peripheral action of opioid analgesia. Opioid receptors are also synthesized in the dorsal root ganglion (DRG) and transported down the axon into the peripheral sites. Endogenous opioid peptide synthesis can be unregulated in the DRG in inflammatory models.

with intractable pain involving the head, neck, shoulder, and arm, can be considered as a supraspinal cordotomy. The outcomes however have been mixed, and complication such as oculomotor dysfunction are widely recognized. It is rarely carried out these days, and other less invasive management strategies are usually preferred.

Spinal cord stimulation

Spinal cord stimulation (SCS) refers to direct application of electrical current to the spinal cord with the aim of achieving analgesia. Empirically, therapeutic use of electricity had been attempted at least as early as 63 BC by the ancient Greeks, who used torpedo fish as the source of electrical current in treating gout. As a modern method of chronic pain relief SCS has been in use since 1966, when Shealy applied an intrathecal monopole electrode connected to the external cardiac pulse generator for the first time and successfully palliated pain in a patient with advanced lung cancer. Shealy thought that direct electrical stimulation of large primary afferents would 'close the gate' to nociceptive signals propagating via small Aδ- and C fibres (see **Box 78.1** on Gate Theory). With the development of fully implantable spinal cord stimulation systems, SCS has become an established method of chronic pain relief (Song et al., 2014). National Institute of Clinical Excellence (NICE) in the United Kingdom recommends SCS for treatment of chronic peripheral neuropathic pain, and the FDA has approved SCS for the management of chronic pain of the trunk and extremities.

How does it work?

SCS implantable system consists of two main parts—electrode lead(s) placed in the epidural space and an implantable pulse generator (IPG) positioned in the subcutaneous pocket (**Fig. 78.6**). Electrodes can be selectively programmed to act as cathode, neutral, or anode, thus creating an electrical current and electromagnetic field which directly affect surrounding spinal structures.

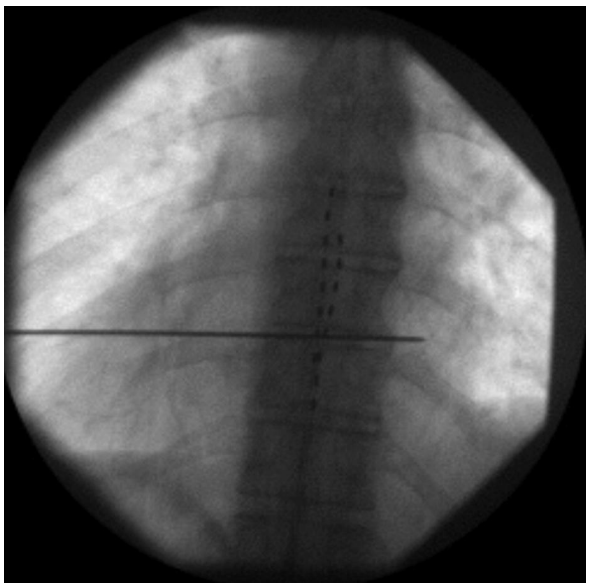

Fig. 78.6 AP view of two percutaneous cylindrical spinal cord stimulation (SCS) electrode leads placed in the lower thoracic epidural space in a in a patient with left radicular leg and bilateral low back pain.

Neurons under a cathode becomes less negatively charged and will depolarize, with resulting bidirectional action potential propagation. The anode creates localized axon hyperpolarization as the membrane becomes more negatively charged. By using different cathode-anode combinations along the lead, it is possible to create an electrical field that achieves paraesthesia in the effective dermatome(s) and concurrent analgesia. Holsheimer used computerized models to explain that stimulation efficacy is determined by several factors that include: the cathode position in relation to physiological midline; electrode polarity; cerebrospinal fluid (CSF) layer thickness under the cathode; axonal diameter and myelination; and axonal orientation within the dorsal columns, dorsal roots, and dorsal horn (anisotropism). More recently, electrical parameters of the stimulation pulse wave have been modified to allow high frequency stimulation, burst pattern stimulation, high current density stimulation, and subthreshold stimulation. Some of these novel simulation techniques do not result paraesthesiae, but still are able to achieve significant analgesic effect.

Mechanisms of action in paraesthesia-based, low frequency SCS have been investigated since the early 1970s. Data on SCS mechanisms have largely come from animal studies, and translation of preclinical data to clinical practice is challenging. While a definitive single mechanism has not yet been determined, several important factors are thought to be involved. First, activation of large diameter Aβ fibres (activating more of them appears to improve outcome), leads to inhibition of dorsal horn WDR neurons. Second, SCS induces release of neurotransmitters, some of which are inhibitory, such as GABA, but also 5-HT (serotonin), glycine, adenosine, and acetylcholine, both pre- and postsynaptically in the dorsal horn. Third, supraspinal pathway stimulation activates descending pain inhibition system resulting in a release of 5-HT and noradrenaline at the synapses with WDR neurons.

These mechanisms have some clinical validation: it is known that paraesthesia (presumably due Aβ-fibre activation) must be experienced by the patient and must overlap the patient's painful areas to result in pain relief from low frequency SCS. The necessity of overlap indicates convergence of Aβ terminal projections in the hyperexcitable regions of the dorsal horn. Also, intrathecal administration of subclinical doses of baclofen, a $GABA_B$ agonist, potentiates the effects of previously ineffective low frequency SCS, thus implicating GABA in the pain relief from traditional, paraesthesia-based SCS.

Recently, 10 kHz high frequency (HF10), paraesthesia-free SCS has been demonstrated to be statistically and clinically superior to traditional low frequency, paraesthesia-based SCS in the relief of chronic intractable back and leg pain. In contrast to low frequency SCS, patients receiving high frequency stimulation do not experience stimulation-induced sensations, and the Aβ-mediated paraesthesia-pain overlap from HF10 therapy targets appears uncorrelated to pain relief. This suggests that Aβ fibres may not play as significant a role in kHz HF-SCS mechanisms, and there is some evidence from preclinical studies that HF10 therapy engages different mechanisms to traditional low frequency SCS.

Indications and contraindications

SCS generally works very well for peripheral neuropathic pain, the most common indication being postsurgical radicular extremity pain. Its effect in treating central neuropathic pain is less

well established. Until recently, the results on low back pain have been mixed. With the introduction of high frequency stimulation and multiple contact electrode leads, it is becoming clear that some forms of low back pain appear to be responsive to SCS.

Common indications for a SCS treatment are presented as follows:

- Chronic neuropathic pain in postlaminectomy syndrome
- Complex regional pain syndrome
- Peripheral neuropathies including post-traumatic and diabetic neuropathy
- Pain due to ischaemic peripheral vascular disease
- Intractable angina
- Sacral stimulation for pelvic pain

Contraindications to SCS therapy include inability manage stimulation; cardiac pacemaker/ICD/intrathecal pump *in situ*; local or systemic infection; immunosuppression; coagulopathy. A relative contraindication is pathology otherwise amenable to surgery (nerve root or spinal cord compression, spinal instability, canal stenosis), though even this has been challenged, for example, recurrent disc prolapse, where revision surgery is known to have higher complications.

Clinical evidence for SCS

The first favourable RCT on SCS vs. reoperation for failed back pain syndrome (FBSS) patients was published by North et al. in 2005. In 2007, a prospective multicentre RCT (PROCESS) compared SCS therapy with conventional medical management (CMM) in 100 patients with FBSS. 48% patients achieved more than 50% pain control in SCS group versus 9% in a CMM group in 6 months (intention-to-treat analysis), followed by 34% and 7% at 12 months and 37% versus 2% at 24 months ($P = 0.003$). Importantly, SCS group patients reported better function with Oswestry Disability Index and quality of life with EQ-5-D questionnaire ($P < 0.0001$) (Kumar et al., 2007). Recently, a prospective multicentre non-inferiority RCT compared conventional tonic SCS with high frequency stimulation, using 10 kHz frequency at low amplitude in intractable low back and leg pain patients. 198 patients were randomized to receive either conventional or high frequency stimulation. High frequency stimulation had better responder rates than conventional SCS in both treating leg pain (78% vs. 51%) and back pain (78% vs. 51%) at 12 months (Kapural et al., 2015).

Practical considerations of SCS therapy

1. *Multidisciplinary assessment of SCS referrals*. Patients need a comprehensive assessment before recommendation for SCS trial. For SCS to be a cost-effective treatment option, careful selection of patients is the key. It is very important for patients to have realistic expectations of SCS therapy. Understanding the limitations of SCS therapy, accepting that SCS is not going to cure their condition or eliminate their pain is a prerequisite for a successful SCS. Engagement with the process of SCS assessment and education is another important predictor of successful outcome.
2. *The choice of a lead*. Electrode leads come in two versions according to their placement technique: percutaneous (cylindrical) and open (paddle) leads. The former is placed into the epidural space through a modified 14 G Tuohy needle under fluoroscopic control and can either be used for on-table testing with subsequent removal at the end of the procedure, or converted into a permanent trial lead by anchoring it to the dorsal fascia, tunnelling and extending for a 1–4-week trial. The advantages of cylindrical leads include ease of insertion and relative non-invasiveness. At the time of writing the standard array of electrodes in a cylindrical lead was 8, with one manufacturer offering a 16-electrode percutaneous lead. The disadvantages of a cylindrical lead are migration, resulting in loss of therapeutic effect, suboptimal electric current spread with stimulation of unwanted targets (e.g. ligamentum flavum) and higher electrical current demands. With the improvement in anchoring technology, migration is less prevalent. Rechargeable IPG technology has also mitigated against the premature battery drainage.

Paddle leads have one active surface and may contain up to 16 electrodes, arranged in up to three vertical rows. They have to be inserted via a small laminotomy, one to two interlaminar spaces below the target level. Wider electrode distribution within a lead may increase the likelihood of successful stimulation and reduce the chance of loss of stimulation effect. Paddle lead migration is uncommon. They also require less electrical current to stimulate the targets anteriorly, as the dorsal surface is insulated. However, placement of a paddle electrode is a more invasive procedure with slightly higher morbidity. Paddle leads occupy more of the epidural space with the risk of spinal cord compression, particularly at the cervical level.

When choosing a lead, one has to consider MR compatibility. At the time of writing most leads and IPGs are certified to be 'MRI Head and Extremity Conditional', thereby allowing patients to undergo MRI head investigations at 1.5 T. One SCS system supplier has developed a full body MRI conditional lead and IPG at 1.5 T.

3. *The choice of IPG*. Currently, all competitors of the SCS market offer rechargeable IPGs, although non-rechargeable IPGs are available. The lifespan of a rechargeable IPG depends on the number of recharge cycles, which is dependent by the stimulation parameters. IPG batteries can last 5–10 years with most available SCS devices. The longevity of an IPG is one of the important variables determining cost-effectiveness of the SCS therapy, and non-rechargeable SCS systems had least favourable cost-effectiveness and high frequency the most (McMahon and Malcangio, 2009).

Complications

Complications have been quoted as high as 34%, though most are minor and correctable. These include loss of analgesic effect with stimulation, loss of stimulation, unwanted paraesthesiae, or dysaesthesia. Causes are lead migration, epidural fibrosis, or development of tolerance, possibly due to spinal cord plasticity. Lead migration is less problematic using modern anchors, but resiting or replacing with a paddle lead may be necessary. With patient education, 'on-off duty' cycling and IPG reprogramming, target stimulation can often be re-captured. There is some data suggesting that burst pattern stimulation may reduce tolerance. Discomfort at the IPG site is common and may require repositioning. Rarely, skin erosion can occur. Other equipment related complications include lead fracture, IPG malfunction, and battery depletion.

Large trial prospective data from trials suggest infection rates as low as 2–3%, in line with other surgical prostheses rates. Percutaneous tunnelled trial, BMI more than 30, and revision surgery are risk

factors. The most common pathogen is methicillin sensitive Staph. aureus. Even superficial infections are concerning and should be treated early and aggressively to prevent neurological infection or device explant. Meticulous surgical technique with appropriate antimicrobial prophylaxis and dressing policy are mandatory.

Neurological complications of SCS therapy are very rare. Most common is inadvertent dural puncture during a lead placement. Injury to spinal cord resulting para/tetraparesis have all be reported. MRI is therefore recommended prior to implant to assess the epidural space and anticipate any potential challenges during lead placement.

Deep brain stimulation

Background

Deep brain stimulation (DBS) has been used in management of complex chronic pain states since 1954 (see Boccard et al., 2015 for review). DBS refers to a method of electrical stimulation of several neural targets thought to be a part of 'pain neuromatrix' in the brain. The hypothesis of DBS analgesic effect arose at least a decade prior to the publication of a 'pain gate' theory from animal experiments and from schizophrenia research. Heath was the first to successfully treat terminal cancer pain over several weeks with intermittent septal stimulation.

Theoretically there are several targets for DBS within a network of numerous brain nuclei, fascicles, and tracts, described as a 'pain neuromatrix'. Historically, medial septal structures were the first to be stimulated. Another important target was identified in the ventroposteromedial (VPM) and ventroposterolateral (VPL) nuclei of the thalamus, from previous data in lesioning in 1973. The periaqueductal grey and periventricular grey (PVG/PAG) were also identified as an important target for analgesia in rodents, and pain relief could be elicited from stimulating this area with DBS. More recently, there has been considerable interest in the anterior cingulate cortex for dissociating pain sensation and its affective component. It seems to work better in central poststroke pain with whole body or hemi-body pain.

How does it work?

The analgesic mechanisms of DBS are poorly understood. The understanding of complex interplay among the multiple parts of pain neuromatrix is still evolving and the hierarchical relationships within the neuromatrix have not been fully elucidated. It is believed that central pain states ultimately result in abnormal firing patterns of neural cells pertinent to pain transmission and perception. There is an ongoing debate as to how exactly neural cell electrophysiology is altered by a continuous nociceptive input. Some argue that it increases synchronous neuron firing frequency. Others, however, stipulate a different mechanism whereby the spontaneous cell firing becomes diminished. DBS either is able to synchronize and 'slow down' abnormal firing in the PAG/PVM and VPM/VPL, or it can augment a suppressed neural activity in the aforementioned structures. Interestingly, DBS of PAG does seem to affect endogenous opioid release and it has been shown that PAG appears to exert ascending modulation upon sensory thalamic nuclei.

Indications for DBS

In theory, any chronic neuropathic pain should respond to DBS. Most work, however, has been conducted with patients suffering from central neuropathic pain unresponsive to multimodal management (Box 78.4). The best results so far have been published in

Box 78.4 Managing pain with drugs—nociceptive vs. neuropathic

Chronic pain control remains a challenge in clinical practice despite improved understanding of the multiple mechanisms at play. The balance of nociceptive input and descending inhibiting output has shifted towards the former, with peripheral and central sensitization often having become major drivers of the neuropathic pain and descending inhibition mechanisms having failed to suppress hyperactivity of the somatosensory system. Pain neuromatrix activation in the brain has altered pain experience, established links with the areas of brain controlling the affect, mood, stress, and emotions. Pain is no longer a physiological nociceptive response; it has become a complex biopsychosocial phenomenon.

Main pharmacological strategies of chronic pain control include:

1. reduction of peripheral nociceptive input and peripheral sensitization;
2. reduction of central sensitization in the spinal cord and prevention of neuroplastic changes in the somatosensory system;
3. augmenting descending pain inhibition;
4. altering pain experience.

The choice of medications for chronic pain control depends of the pain mechanism. In nociceptive pain the most important strategy is the reduction of nociceptive input. non-Steroidal anti-inflammatory drugs (NSAIDs) and opioids are the most effective medication groups. NSAIDS reduce inflammation by inhibiting COX-1 and COX-2 enzymes and thus reducing pro inflammatory prostaglandin synthesis at a tissue injury site. This way peripheral sensitization is reduced. Opioids act on multiple targets in the e peripheral nervous system (PNS) and CNS and the net result reduce peripheral nociceptive input at the dorsal horn. They also reduce signal transmission via the second order neuron and enhance descending pain inhibition at the RVM. Importantly, they also alter the pain experience.

Once the changes in the somatosensory system have occurred (e.g. upregulation of TPVR1 and 2, voltage gated Na + channels, $\alpha 2\delta$ subunit of calcium channel presynaptically, activation of WDRs in the dorsal horn, activation of AMPA and NMDA receptors, glia, and astrocytes, as well as reduced activity of $GABA_A$ receptors postsynaptically, sensitization of second order neurons, inhibition of serotonergic and noradrenergic descending pain inhibition systems, and activation of pain neuromatrix in the brain) other strategies of pain control have to be used.

Peripheral desensitization can be tried with capsaicin cream or patch (acts on vanilloid receptors TPVR1 and 2 presynaptically), local anaesthetic applications (i.e. LA cream, lidocaine plaster), systemic Na + channel inhibitors (i.e. carbamazepine in TGN), gabapentinoids (i.e. gabapentin and pregabalin).

Central de-sensitization can be attempted with gabapentinoids (acting in the brain on the $\alpha 2\delta$ subunit of calcium channel and thus enhancing a descending noradrenergic pathway), serotonin and noradrenalin re-uptake inhibitors (tricyclic antidepressants, venlafaxine, duloxetine, tramadol), selective noradrenalin re-uptake inhibitor tapentadol, non-selective NMDA antagonist (ketamine, methadone), a2-agonist clonidine. Opioid agonists are not as effective in the management of central sensitization and neuropathic pain, therefore should not be the mainstay of neuropathic pain control. Over-reliance on opioid drugs may lead to development of tolerance and/or psychological dependence (addiction) that will result in dose escalation and may lead to serious iatrogenic complications (constipation, respiratory depression, opioid-induced hyperalgesia in the dorsal horn, suppression of the adrenopituitary axis, immunosuppression, cognitive deterioration).

patients with atypical facial pain, central poststroke pain, brachial plexus avulsion pain, and postamputation pain/phantom limb pain. There have been case reports on the effectiveness of DBS in spinal pain/FBSS.

Evidence of DBS efficacy

There have been two multicentre trials conducted for DBS in pain management. Both trials suffered from important design and data collection flaws as well as patient heterogeneity and high attrition rates. Neither trial was able to report more than 50% of pain relief for at least 12 months in 50% or more of the trial subjects—a primary outcome set out by FDA. As a consequence, DBS has no FDA approval in the United States. Since then there have been more publications including a randomized placebo-controlled trial. NICE in the United Kingdom has approved the use of DBS for treatment of refractory chronic pain for well selected patient group who have failed other treatments.

Complications

The clinically significant complications of DBS could be classified as surgical complications, hardware-related complications, and stimulation-dependent complications. Surgical complications of DBS surgery include intracranial haemorrhage (4%), infection (12%), electrode misplacement and, rarely, death. Hardware-related complications include electrode fracture, electrode erosion, and infection. Stimulation-dependent complications are the effect of undesired modulation of neural circuits adjacent to the targets of neuromodulation.

Motor cortex stimulation (MCS) for managing refractory central and peripheral deafferentation pain syndromes first emerged in the 1990s and has been used with some success in some small studies. The mechanism by which MCS might operate is unclear, though it is postulated it may work via activation of reciprocal pathways between motor and somatosensory cortex, that leads to sensory inhibition, or possibly through the activation of limbic pathways. There is some scepticism about its long-term benefits, but transcranial magnetic stimulation may emerge as a non-invasive screening tool for patient selection.

Conclusions

Chronic pain remains a huge problem, spanning all disciplines of medicine. The last 25 years of pain research has redefined our understanding of sensory physiology and pain biology. No longer is pain and nociception thought to be mediated via hard wired, fixed circuitry that can be 'rewired' surgically, and many of the older surgical techniques for managing chronic pain have fallen from favour. With an increased understanding of pain neurobiology and maladaptive sensory plasticity come new opportunities for effective and evidence-based interventions (Yekkirala et al., 2017). From a surgical perspective, stimulation-based techniques have produced the most optimism in recent times, and this field will continue to develop rapidly. There may still be a role for destructive techniques for well selected patients in experienced hands, but the potential for failure and the irreversibility of these techniques has made them less attractive in the current climate of medicine.

Cranial nerve vascular compression syndromes

Marc Sindou and George Georgoulis

Introduction

Along the last decades it has become apparent that a large number of so-called 'essential' (i.e. apparently primary) cranial nerve (CN) 'hyperactive' syndromes originate from chronic neurovascular conflict (NVC), microsurgical vascular decompression (MVD) thus being the first surgical option for these dysfunctional syndromes.

Hyperactive CN syndromes affect all CNs from third to twelfth.

- Trigeminal neuralgia (TN) is by far the most frequent syndrome. Nowadays there is a general consensus that main cause is a NVC on the sensory root of the fifth CN, classically but not always at the root entry zone (REZ). Surprisingly, the motor root is rarely affected.
- Hemifacial spasm (HFS) is also frequently observed, almost always caused by an arterial compression of the seventh CN, nearly always at REZ.
- Vago-glossopharyngeal neuralgia (VGPN), also due to a NVC but on the ninth and/or the tenth CN, is very similar to TN with regard to pain features and related treatments. Prevalence is 1% compared to TN.
- Alterations of the eighth CN—which has the longest central myelin portion of all CNs, from brainstem to internal auditory canal, may be at the origin of tinnitus (cochlear nerve) and vertigo (vestibular nerve). Both disorders are frequent and their pathophysiology various. Mechanisms are pathological insult(s), of any kind, lesions being responsible for peripheral deafferentation followed by central synaptic reorganization, similar to what can be observed at the origin of many types of neuropathic pain. A number may be related to NVC, the diagnosis of which is sometimes difficult to ascertain.
- Hyperactive syndromes of the motor CNs others than the facial nerve are infrequent. Abnormal movements of the motor ocular CNs (third, fourth and sixth) are most often in relation with causes others than NVC.
- Muscular spasms attributed to the masticatory motor root of the Vth CN have been only sporadically reported. Spasmodic torticollis, hypothesized by some to be due to NVC of the eleventh CN, should rather be classified within the frame of dystonias/dyskinesias. Origin is likely brainstem/basal ganglia dysfunction rather than accessory nerve compression. Regarding the hypoglossal CN, only one publication has reported on hemi-lingual spasm by NVC on the twelfth root.
- Vascular compression of the ventrolateral medulla, ventrally to the ninth to tenth CN REZ, has been hypothesized as a possible cause of neurogenic essential blood hypertension.
- Finally, in a few cases several CNs in the same individual can be affected by hyperactive dysfunction.

Hypotheses on neurophysiological mechanisms are summarized in **Box 79.1**.

Hemifacial spasm

Definition of hemifacial spasm (HFS) is clinical: chronic, involuntary movements on one side of the face characterized by 'twitching' spasms and synkinesis of the muscles innervated by the facial nerve. Diagnosis of primary HFS must fulfil the three following criteria: (1) not a sequela of facial palsy; (2) chronic in evolution and limiting; (3) normal investigations except for the presence of a vascular compression of the seventh CN, generally at its REZ.

Pathophysiology

There is now considerable evidence that primary HFS is related to functional changes (hyperactivity) in the facial motor nucleus, that originate from a pulsatile compression of the facial nerve at REZ (Gardner, 1962; Gardner and Sava, 1962; Møller and Jannetta, 1984; Sindou, 2005). This central hyperactivity of the nucleus would produce motor discharges that may be provoked by a variety of peripheral stimuli as well as by emotional events conveyed through the brainstem reticular formation. Such putative mechanisms are consistent with the clinical and the electrophysiological features of the spasms as well as with the imaging and the intraoperative findings of a neurovascular compression at the facial REZ. Over the last three decades microvascular decompression (MVD) has proved to be valuable to cure the disease (Barker et al., 1995). An abundant

Box 79.1 Hypotheses on neurophysiological mechanisms

Most accepted mechanisms for cranial nerve (CN) hyperactive syndromes due to NVC are several and, interestingly, rather complementary.

Chronic pulsatile compression of the root would generate ectopic stimuli that are transmitted to neighbouring fibres through focal zones of demyelination. These demyelinated zones would behave like neosynapses and be responsible for ephaptic transmission, in other words the epicentre of 'short circuits' with 'cross-talk' phenomena between fibres (Gardner, 1962). This could explain the triggered and irradiating clinical manifestations. Classically the NVC are preferentially situated at the so-called REZ (root entry/exit zone). To our knowledge there is no 'official' definition of the REZ. However, it is generally accepted that REZ corresponds to the portion of the root from brainstem to the transitional zone (TZ), which is the junction between the portion of the root with myelin of central type and the portion of the root with myelin from Schwann origin (**Fig. 79.1**). The central portion and TZ are hypothesized to be more 'excitable' structures. Actually, not all NVC are found at REZ; some are more peripherally situated. For those later NVC, observation under the operative microscope frequently showed a groove with a greyish aspect marked by the compressive vessel, namely a pulsatile artery, or also and not rarely a (non-pulsatile) vein testifying of a focal demyelination.

Mechanical pulsations and focal demyelination should not be considered as the sole source of the dysfunction. The locally generated ectopic influxes would induce, by retrograde firing of the corresponding CN nucleus (i.e. through a 'kindling-like' phenomenon), a hyperexcitability and hyperactivity of the nucleus cells. This hyperactivity generated in the central nervous system is consistent with the epileptic-like clinical manifestations of many of these CN hyperactive syndromes, as well as of their particular responsiveness to anticonvulsants.

Besides, there is no doubt that other mechanisms remain yet undiscovered. Genetic, humoral, hormonal, and also psychological factors, likely play a role in the pathogenesis of these complex—apparently essential—neurological disorders.

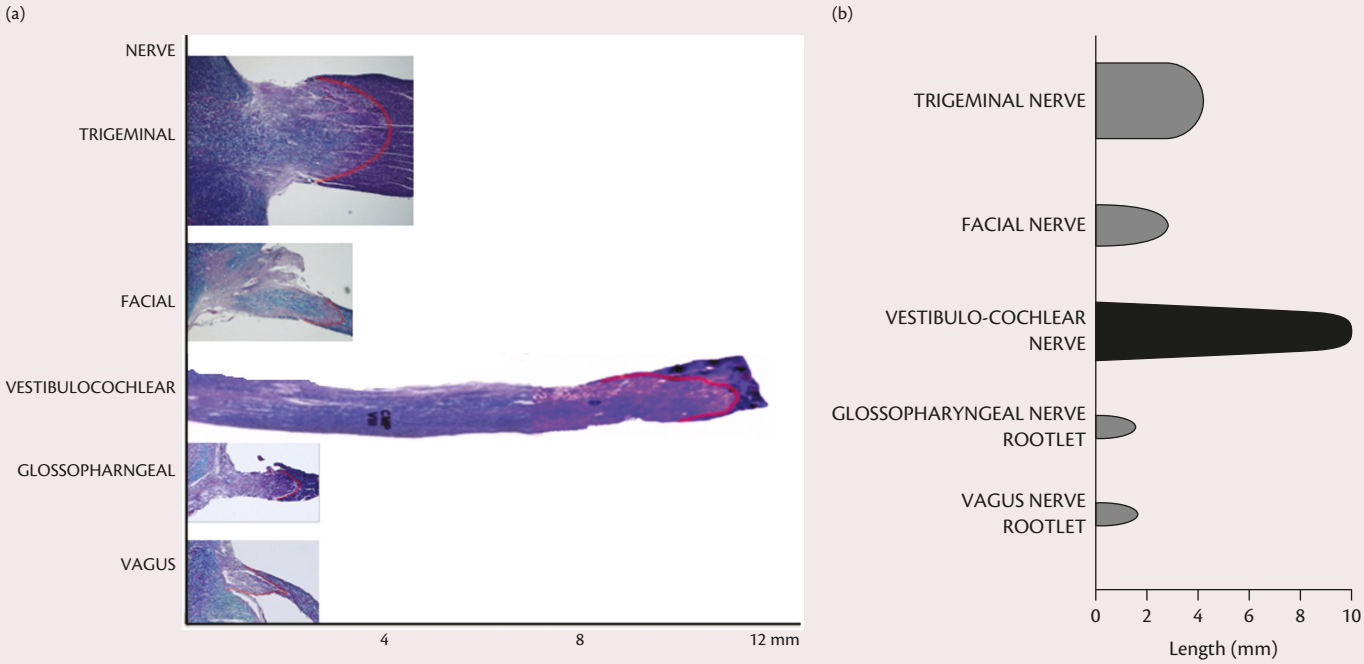

Fig. 79.1 (A) Photomicrographs of longitudinal sections stained with Luxol fast blue, of trigeminal, facial, vestibulocochlear, glossopharyngeal, and vagus roots, at same scale for comparison. The transitional zone (TZ) between central myelin portion and myelin of Schwann portion is underlined. (B) Comparative drawings of central myelin portions, obtained from mean values of the length (with diameter), of the corresponding roots.

literature has been produced on findings, techniques, and results; references can be found in the following publications (Huang et al., 1992; Sindou et al., 1997; Sauvain et al., 2001; Sindou and Keravel, 2009b; Li et al., 2016).

Diagnosis

Prevalence (in the USA) is 1/100 000. The left side is affected twice as often as the right, and women are affected twice as often as men.

In typical primary HFS, spasms usually begin as slight intermittent unilateral twitching of the orbicularis oculi muscle; lower facial muscles are involved only secondarily.

Electromyography (EMG) recordings produce a typical electrophysiological signature: clonic facial muscle contractions, synkinesis, lateral spread evoked responses.

Imaging is useful for confirming that HFS is primary in nature and due to neurovascular compression. The compressing vessel(s), generally an artery: the anterior inferior cerebellar artery (AICA), the posterior inferior cerebellar artery (PICA), and/or vertebrobasilar artery (VBA), can be reliably depicted on high-resolution MRI combined with MR-angio (MRA). 3-D T2 offers good delineation of the facial nerve. Important, there might be several false-positive images, vascular contacts with CNs being common in asymptomatic patients. The responsible artery(ies) are generally located at brainstem in ventrocaudal location to the facial REZ.

Surgical management

Pharmacological treatments show poor efficacy. The first option is repeated injections of Botulinum toxin, but when they become ineffective MVD is the only recourse.

The MVD procedure was pioneered by Gardner (Gardner, 1962), then subsequently codified and popularized by Jannetta (Jannetta et al., 1977). There may exist one or multiple arterial compressions in the same individual. In our series of 280 patients, PICA, AICA and/or vertebral artery (VBA) were the responsible vessel(s) in 61%, 56% and 27% of the cases, respectively, multiple compressions being found in as many as 40% of our patients (Marneffe et al., 2003). Missing a vessel especially at brainstem could be the source of surgical failure.

With most teams the patient is operated in the lateral decubitus position. Approach is a 'keyhole'-type retromastoid craniotomy, of 2 cm to 1.5 cm in size, posterior to the tip of the mastoid process so that the facial nerve be reached from below, inferolaterally to the cerebellar flocculus (**Fig. 79.2**). The infraflocculus route is important for two reasons. First, NVCs are generally located ventrocaudally at brainstem. Second, a lateral-to-medial retraction of the cerebellar hemisphere would exert stretching on the eighth nerve with risk on hearing. This is warned by an increase in latency of peak III and V on intraoperative BEAP recordings (Grundy et al., 1982; Møller and Møller, 1989; Sindou et al., 1992; Polo et al., 2004).

During mobilization of the compressive artery(ies), care must be taken not to avulse perforators and not to manipulate AICA as well as the labyrinthine artery. Mechanical vasospasm could be the cause of cochlear ischaemia. A warning sign is decrease in amplitude of peak I on BEAPs recordings (Sindou et al., 1992; Polo et al., 2004). The conflicting loop(s) is (are) maintained apart with a piece of material: Teflon in our practice. *('PTFE Felt' is used to make bundles or balls by stripping filaments from mattress. 'Edwards Outflow Tract Knitted PTFE' is used to make (rigid) plates for interposition. 'Sauvage Knitted Polyester' is used to make (supple) sheets for interposition. (Manufactured by Bard Peripheral Vascular, Inc. 1625 West 3rd Street, Tempe, AZ 85281 USA, https://www.crbard.com).* Attention should be brought not to exert any neocompressive effect on the facial and/or the vestibulocochlear nerve, as well as not kinking the artery(ies). Regular irrigation with (a few) droplets of 10% papaverine in normal saline solution is wise to release constrictive vasoreactions. Excessive use of concentrated solution would be toxic because of the very acid pH of papaverine.

In patients with HFS, stimulation of the facial nerve, one of its branches, gives rise to repetitive and spreading EMG responses in the facial muscles, innervated by the other branch. Intraoperative running EMG recordings of lateral spread responses (LSR) during MVD, was advocated by Møller and Jannetta to ensure that adequate decompression has been achieved (Møller and Jannetta, 1987; Mooij et al., 2001). In our series because long-term relief was obtained even in patients in whom LSR remained present at end of MVD we doubt about that reliability of LSR monitoring (Hatem et al., 2001).

Results

Long-term cure rate is reported to be 85% to 95% according to authors. Cure may be delayed by several months to one year (Goto et al., 2002; Sindou and Keravel, 2009a; Zhong et al., 2015). In our series of 280 patients, cure rate was 87% at seven years of FU, of whom in 12% cure was delayed by several months. Because of this frequency, we do not recommend early re-operation until at least one year has passed. When complete relief is obtained, recurrence is infrequent, at a rate of 1–2% according to series.

Delayed cure strongly supports that HFS is not only due to mechanical pulsations of an elongated artery against the REZ of the nerve. Demyelination of fibres and hyperactivity in the facial motor nucleus induced by the chronic vascular compression likely play a role. Delay could be explained by the time necessary for reversal of the plastic electrophysiological changes, especially those in the nucleus that are considered as having caused the symptoms (Møller and Møller, 1989; Sindou, 2005).

MVD rarely has major complications. From literature reviews, an indicative list of risks can be given as follows. Mortality was less than of 1% and cerebellar infarct or haemorrhagic complication in the order of 0.50% ± 0.30. CNs most at risk are the eighth, and the seventh, and to a lesser extent the lower CNs. Permanent hearing loss with sufficient or non—sufficient residual function occurred in the range of 2.45–15.90% and 1.18–2.60%, respectively. Permanent facial nerve palsy, of any degree, initial and irreversible, ranged between 0.8 and 5.0% according to series. A delayed facial palsy that generally occurred around the end of the first post-op week, was observed in as many as 7.30% of the patients in the reporting articles. This symptom—whose mechanism remains unknown –was totally reversible within several weeks to a few months in almost all patients. Lower CN disturbances, manifested by hoarseness, dysphagia, swallowing difficulties, were observed in 0.44% to 2.18% of the patients. Complications related to cerebrospinal fluid (CSF) leakage are: middle ear effusion, pseudomeningocele, and rhinorrhoea, with eventual meningitis. Occurrence is minimized by careful tight closure.

Trigeminal neuralgia

Definition of trigeminal neuralgia (TN) is clinical. According to the Classification Committee of the International Headache Society, TN—in its *typical presentation*—is characterized by recurrent unilateral brief electric shock-like pains, abrupt in onset and termination, limited to the distribution of one or more divisions of the trigeminal nerve, and triggered by innocuous stimuli (Headache Classification Committee, 2013). There may additionally coexist a background of continuous facial pain; this presentation is termed *atypical trigeminal neuralgia*. Whether its clinical presentation is typical or atypical, TN may develop in the absence of apparent cause (= primary) or be a result of a neurological or other disease (= secondary). When TN develops with no identifiable cause other than neurovascular compression, it is named *classical*. When it remains of unknown origin, it is considered as *idiopathic*.

Diagnosis

- *Prevalence* is 7/10 000. Incidence is five new cases per year for 100 000 population.
- *Diagnosis* relies on clinical examination. Stimulus dependence (i.e. triggered pain), is a mandatory criterion of TN. Although some mild sensory abnormalities may be found especially in longstanding TN, absence of sensory deficit is essential for the diagnosis. Noteworthy, in long-lasting classical TN with background of facial pain (i.e. atypical forms), the paroxysms may have disappeared or been masked by medical treatment. Some authors classify TN into type 1 pain, consisting of the lancinating type, and

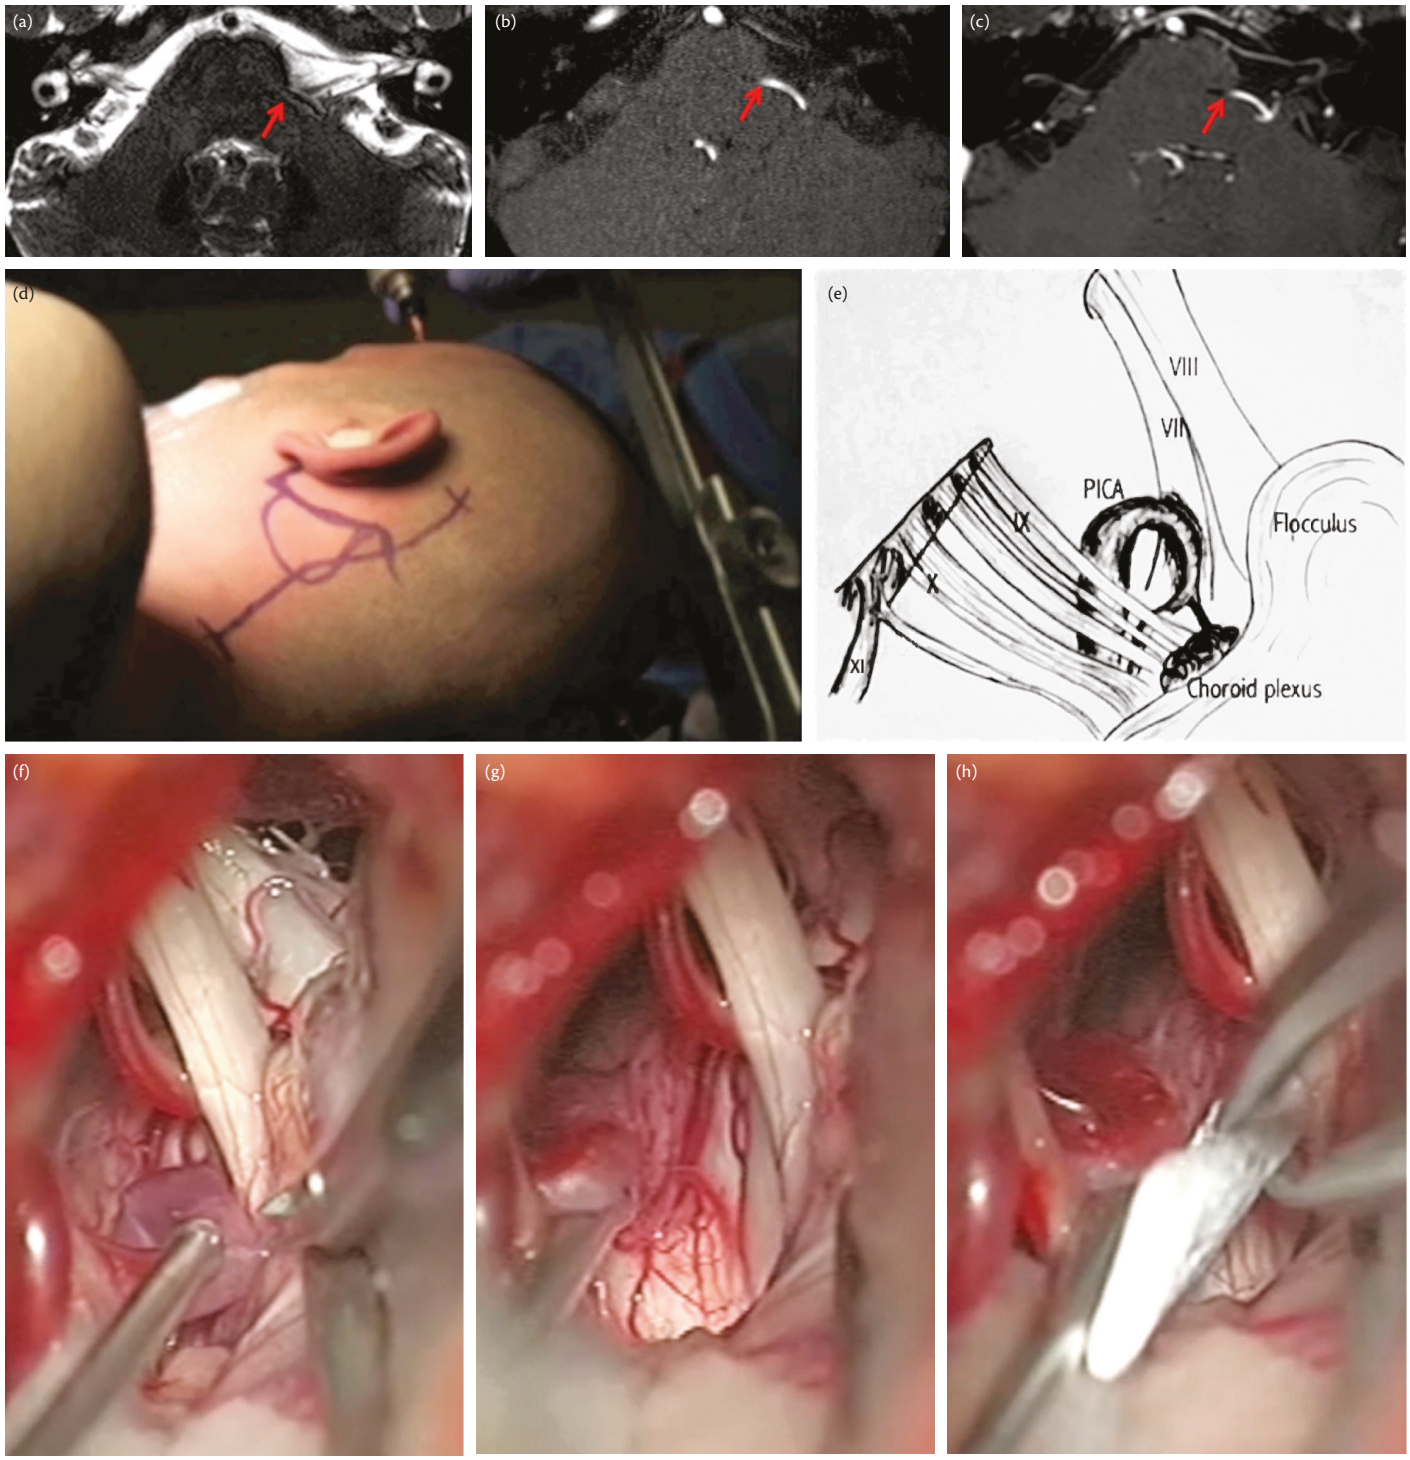

Fig. 79.2 Hemifacial spasm (HFS) on the left side.
MRI findings: Loop of posterior inferior cerebellar artery (PICA) in left facial REZ embedded in brainstem, on T2-sequence (A), clearly visible on TOF-angio sequence (B) and on T1-gadolinium sequence (C).
Surgical approach, through craniectomy performed posterior to tip of mastoid process (D), to access the facial REZ from below, that is, along the lower CNs (eleventh, tenth, and ninth) and the choroid plexus emerging through Luschka foramen at upper part of the cerebellomedullary fissure. The neurovascular conflict is located ventrocaudally to facial REZ and at adjacent brainstem (E).
Microsurgical steps: PICA loop compressing facial REZ, the later not being seen because masked by cochleovestibular nerves (F); loop detached from facial REZ (seen ventrally to the eighth nerve), with a greyish aspect (G); loop maintained away by a piece of Teflon semi-rigid material (1 cm in length, 5 mm in width) (H).

type 2 pain, which can be constant, aching, or burning (=Burchiel's classification). These two types can overlap in the same patient. It is important to exclude other facial pain syndromes such as trigeminal deafferentation pain, which may be the result of previous treatment, and SUNCT (short-lived, unilateral neuralgic headache with conjunctival injection and tearing) particularly following treatment failure and consideration of reintervention.

- *Response to anticonvulsants*—primarily carbamazepine or oxcarbazepine—at least at the onset of the disease, is an important additional criterion.
- *Multidisciplinary investigations* of the odontostomatologic, ear, nose and throat (ENT), maxillofacial, ophthalmologic and neurologic specialties are crucial to rule out secondary TN that would require specific treatment. In fact, secondary TN may remain misdiagnosed under the mask of a clinical typical presentation resembling primary TN, especially in neurologic diseases such as multiple sclerosis or cerebellopontine angle tumours.
- *Imaging* of the trigeminal root is a prerequisite for the choice of the procedure. The three following high-resolution sequences: 3D T2 high-resolution, time of flight (TOF) MR-angiography, T1 with gadolinium, in association because of their complementarity, allows—with a 1.5 Tesla machine—to depict NVC with a sensitivity of 96.7% and a specificity of 100% (Fig. 79.3A–C and Fig. 79.4A–C) (Leal et al., 2010).

The 3D–T2 sequence obtains fine images of the root. The cerebrospinal fluid has a hyperintense signal and the other structures of the cerebellopontine angle have a hypointense signal, achieving a cisternography-like exploration. Limitation is the absence of differentiation of signals between vessels and nerves. The 3D TOF-MRA if performed with a presaturation filter, visualizes only high-flow vessels (i.e. principally the arteries). The 3D-T1 sequence with gadolinium depicts arteries and veins, both being enhanced by contrast medium. Comparison of the latter two sequences allows differentiating veins from arteries.

Depicting cross-compressive veins is important (Matsushima et al., 1983; Dumot and Sindou, 2015). In our series they accounted for 39%, either separately in approximately one-fourth or in association with an elongated cerebellar artery in approximately three-quarters (Dumot and Sindou, 2015). Veins may belong to the superior petrosal venous system in the cistern (60%) or be a transverse inferior vein at exit of the root from the porus of Meckel cave (40%).

This MRI protocol also permits prediction of the degree of vascular compression, which can be: simple contact (grade I); distortion of the root (grade II); marked indentation in the root (grade III). This was possible in 84.6% of our patients (P <0.01) (Leal et al., 2010).

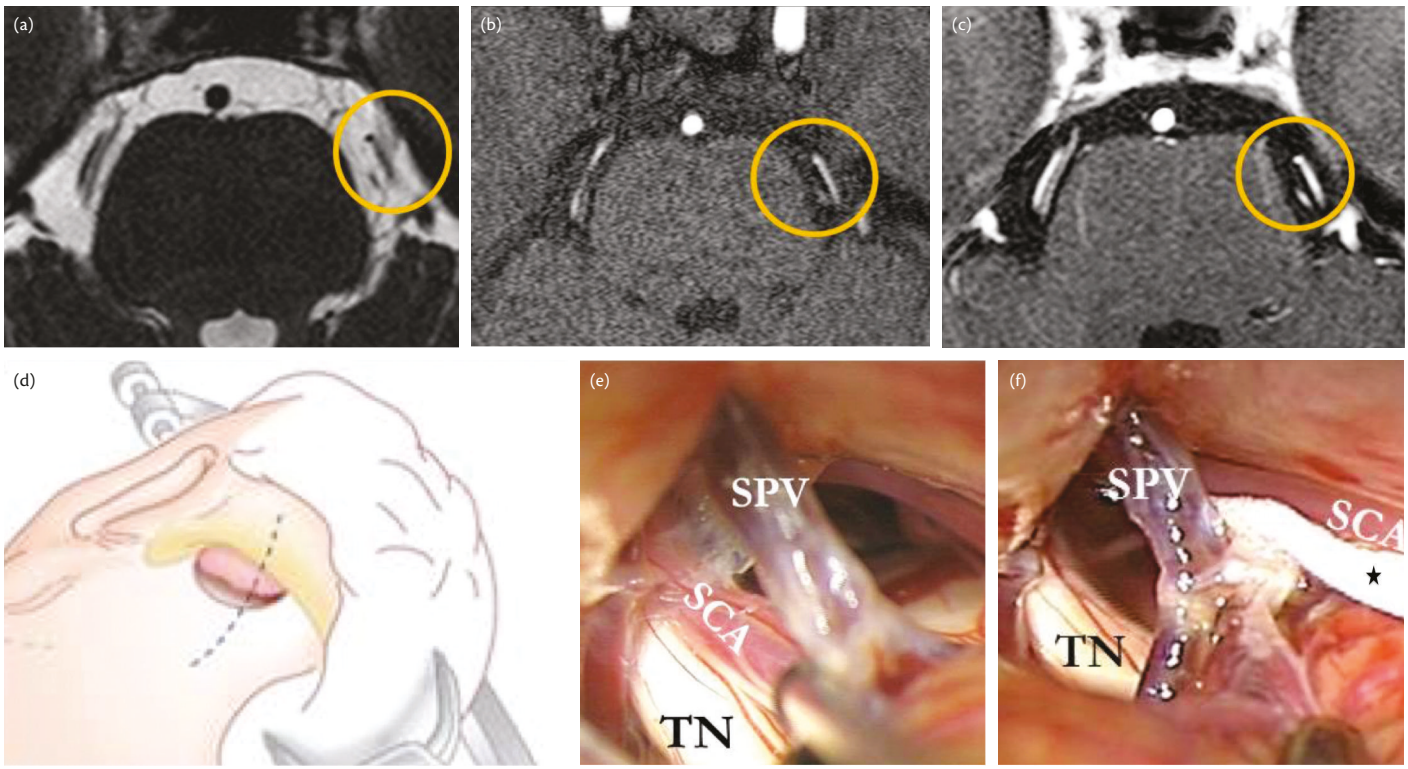

Fig. 79.3 Neurovascular conflict (left-sided TN) from the superior cerebellar artery (SCA).
(A–C) Imaging of a pure arterial compression of the trigeminal root by the SCA. (A) 3D-T2 high-resolution sequence showing the root crossed by the conflicting vessel; (B) 3D time of flight (TOF)-angio; (C) 3D-T1 sequence with gadolinium. Note that the identifiable conflicting vessel seen in T2 is not only visible in T1 + gadolinium, but also in TOF-angio, leading to conclude to a high-flow vessel (i.e. rather arterial, namely the SCA). (D–F) The microsurgical approach via an infratentorial-supracerebellar route (on the left side). The SCA is stuck to the superior aspect of the root (grade II of compression) (E). After the artery is detached and pushed away from the root, the SCA is maintained at distance by a small piece of Teflon (asterisk) (F). TN, trigeminal nerve; SCA, superior cerebellar artery; SPV, superior petrous vein. Note that the SPV and its affluents were preserved. Also note that the Teflon plate (hold by the SPV) does not touch the trigeminal root ('no neocompression').

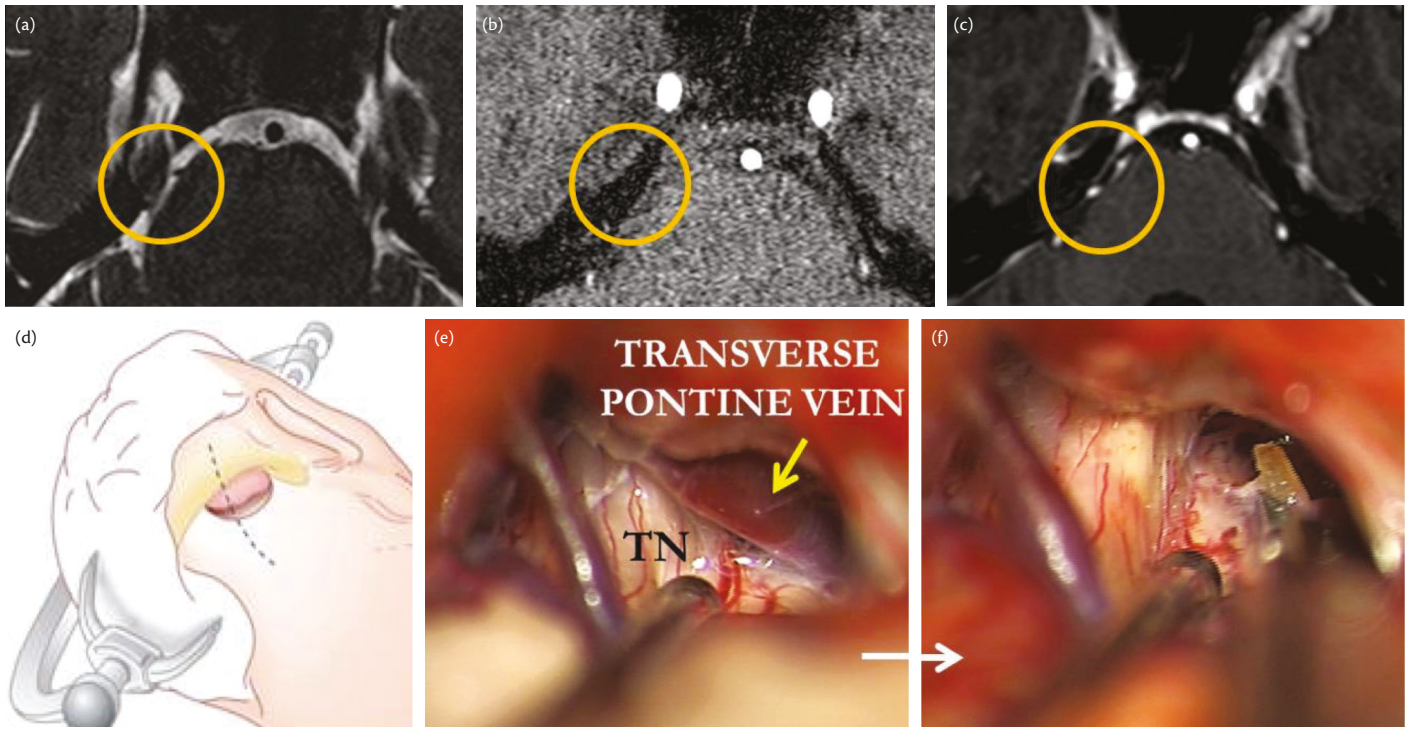

Fig. 79.4 Neurovascular conflict (right-sided TN) from pure venous compression, namely the inferior transverse vein. (A–C) Imaging of a pure venous compression by transverse (pontine) vein after exit of root from the porus of Meckel cave. High-resolution T2 axial view shows the root being crossed by the conflicting vessel. (A) The identifiable conflicting vessel on T2 is not visible in TOF-angio sequence, but apparent on T1 with gadolinium sequence, which is evocative of a pure venous conflict. Note the small size of the cerebellopontine angle cistern. (D–F) Microsurgical approach via an infratentorial-supracerebellar route (F). The transverse vein (arrow) is seen compressive to the inferior aspect of the trigeminal root as it exits from the porus of Meckel cave (E), TN: trigeminal nerve. Coagulation and division of the vein was considered indispensable for release of the trigeminal root compression (F).

With a 3 Tesla machine, images are finer and sensitivity rate even higher: 97.4% in our study, which can be useful for detection of small venous conflicts (Leal et al., 2011).

High-resolution MRI also reliably reveals morphological abnormalities of the trigeminal root, namely, global atrophy, angulation on crossing the upper petrous ridge at the porus of the Meckel cave (MC) and abnormalities of the posterior fossa, such as platybasia, Arnold-Chiari malformation, cisterns of small capacity, ….

Anatomical findings and their functional consequences

According to literature, a NVC can be found at the origin of most primary TNs, in 76.3% to 100% according to series, 90.5% on average. In our initial study on anatomical findings at surgery, a vessel was found in relation with the TR in 97% of the explored patients (Sindou et al., 2002). There was a compressive artery in 90.70% of the patients, whereas in the remaining 9.30% the conflict was found exclusively venous. The responsible elongated arteries were the superior cerebellar artery (SCA) in 88%, the AICA in 25.1%, the VBA in 37.8%, so that more than one compressive vessel was found in 37.8% of the patients. Failing to identify all conflicts at surgery could be source of failure or recurrence.

In same as well as in other personal studies (Sindou et al., 2002; Sindou et al., 2007; Dumot and Sindou, 2015), the NVC was situated at REZ as classically described in only 50% of the cases, at the midcisternal portion of the root in 40%, and more peripherally at the porus of MC in 10% (Fig. 79.5). In the latter situation the conflicting vessel, most often a transverse vein, marked a strong indentation on the root, with a greyish decoloration, typical of focal demyelination. Complete exploration of the entire root, from brainstem to porus of MC, is wise not to miss conflicts situated peripherally.

In a recent study strictly devoted to implication of veins, a clear venous compression was found in 38.7%, either alone (in one-fourth) or in association with an artery (in the other three-quarters) (Dumot and Sindou, 2015).

Determination of the degree of compression on preoperative high-resolution imaging is important as it plays a role in the outcome. In our KM study, a marked vascular compression, of grade III or II, found in 49.2% and 33.2%, respectively, was associated with a high success rate at 15 years of FU: 88% and 79%, respectively. Conversely, compression of grade I, found in 17.2%, was correlated with a 65% cure rate only (Sindou et al., 2007). The grade of compression, which can be predicted with reliability (P <0.01 for high grade of compression), should be taken into account for decision-making (Leal et al., 2010).

Anatomical abnormalities of the trigeminal root or the posterior fossa are frequently associated to vascular compression (Sindou et al., 2002; Sindou et al., 2007), (Parise et al., 2010; Parise et al., 2013). According to our observations, in 42% the TR had a significant degree of global atrophy, in the order of one to two-thirds reduction in calibre with a ruban—instead of a cylindrical—shape, testifying a coexisting neuropathy from likely degenerative origin. In 18.2%, arachnoid was thickened, with strong adhesions to the

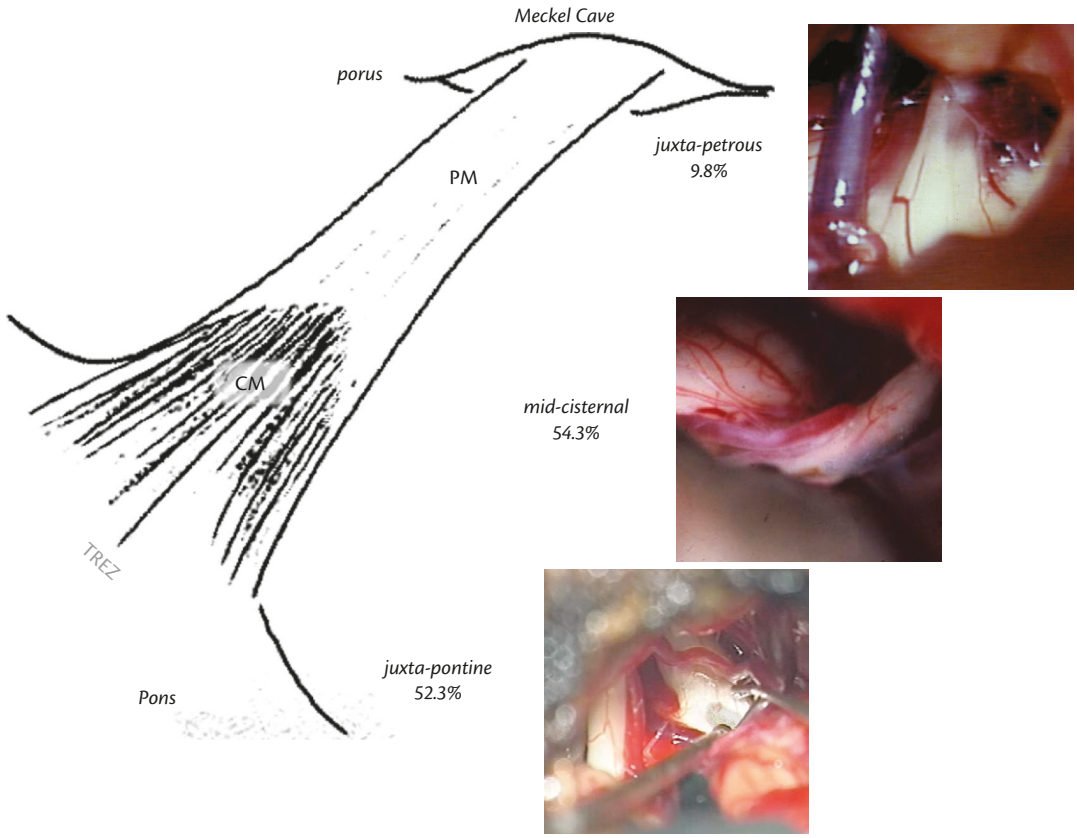

Fig. 79.5 Repartition of the neurovascular conflicts (NVC) in the patients with trigeminal nerve explored for MVD, according to respective situations at Trigeminal REZ (juxta-pontine), at mid-third of the root (midcisternal) and at exit of root from porus of Meckel cave (juxta-petrous). In 37.8% of the patients NVC were multiple in same individual. CM, central myelin, PM, peripheral myelin. Examples of operative views of NVC: Juxtapontine: right NVC inferiorly to trigeminal root entry zone (TREZ) from AICA loop (retracted with microaspirator), of grade III of compression (i.e. strong engrooving with greyish aspect of focal demyelination); Midcisternal: right NVC superiorly to midportion of the root from SCA, pushing root down (grade II of compression); Juxtapetrous: right NVC inferiorly to root at exit from porus of Meckel cave due to inferior transverse vein (grade III of compression). Note the marked greyish zone of focal demyelination.

root. In 12.6% the root had a marked angulation on crossing over the petrous ridge at exit from MC, especially when the cerebellum was atrophic, which corresponds to the so-called sagging phenomenon (Gardner et al., 1956). In 3.9% the root was compressed by being squeezed between the pons and the petrous bone within a 'virtual' cerebellopontine angle cistern due to the small size of the posterior fossa. These abnormalities must be taken into account for decision-making, as well as for the design of the surgical procedure.

Surgical methods and corresponding results

Criteria for neurosurgical indication are basically, first, investigations for eliminating a causative disease that would require specific treatment, second, neuralgia refractory to the medical treatment or intolerance due to major side effects including asthenia.

There is a variety of surgical options that the patient may be offered according to his (her) particularities, either of lesioning nature by means of percutaneous or radiosurgical techniques, or conservative with the MVD procedure.

Microsurgical vascular decompression

In 1934 Dandy, who pioneered juxtapontine rhizotomies for TN, published his observation on frequent compressions of the TR by a neighbouring elongated artery (Dandy, 1934). Surprisingly he did not reach the point to free the root from the vascular compression. It was Gardner in 1959 who performed the first decompression (Gardner and Miklos, 1959). In fact the method was really promoted by Jannetta through his famous publication of 1967 (Jannetta, 1967). In his paper the TR was accessed via the subtemporal-transtentorial approach. Tribute for the easier and safer retromastoid approach must be paid to Hardy (Provost and Hardy, 1970). The microvascular decompression (MVD) method was then codified and popularized worldwide by Jannetta through a large number of publications (Jannetta, 1976).

Operative steps for MVD are illustrated in **Figure 79.6**.

Offending vessel(s) may be more than one in the same individual, in the order of one-third of the patients (Sindou et al., 2002). For not missing multiple conflicts, the entire root must be explored from REZ at brainstem to porus of MC and freed from all arachnoid adhesions. Interposition of material to maintain the conflicting vessel away should not be 'neocompressive' (**Figs. 79.3D–F and 79.4D–F**) (Sindou et al., 2008).

Literature results are summarized in **Table 79.1**. According to the studies with a minimal average FU of 5 years and K-M analysis, MVD provides a high rate of pain relief (Tatli et al., 2008). In the largest series of 1185 patients operated on by Jannetta, probability of an excellent outcome ten years after surgery is of 70% (Barker et al., 1996).

Fig. 79.6 Microvascular decompression in patient affected with right TN due to mixed neurovascular conflicts (NVC), namely superior cerebellar artery (SCA) and vein from the superior petrosal venous (SPV) system. Illustration of patient's positioning, approach and surgery. (A) Lateral decubitus positioning with (moderate) traction on shoulder. Operating table in (slight) anti-Trendelenburg inclination to decrease cephalic extremity venous pressure. (B–D) Note 15° lateral angulation of neck/head toward contralateral side (B), 15° contralateral rotation of head (C) and landmarks of craniectomy (hatched area) below occipital crest/transverse sinus and posterior to base of mastoid process/sigmoid sinus (D). Cutaneous incision is 1 cm medial to the bisector of the angle formed by the nuchal line and the posterior aspect of the mastoid process. (E–I) MRI T1 + gadolinium sequence shows SCA loop on the ventromedial aspect of the trigeminal root and veins from the SPV system in contact with the dorsolateral aspect of the root. Drawings (F, G) and operative views (H, I) show trigeminal root before and after microvascular decompression. Asterisk, loop of SCA; V, compressive branches of SPV.

Table 79.1 Summary of results (from literature) of the various surgical methods for trigeminal neuralgias

	Immediate pain relief: Range (average)	Long-term pain relief: Range (average)	Failure and neuralgia recurrence rate mortality rate	Side effects/Complications Range (average) T = transient, P = permanent	Advantages vs. disadvantages
Thermo-rhizotomy N = 7483 pts FU: 3–26 y (9 y)	81–99% (94%)	20–93% (60.4%)	39.6% (+): 0.1% by carotid injury	Numbness (permanent): 5–98% Masticatory deficit (transient): 4–24% Corneal hypoesthesia (permanent): 5–18% (12%) Keratitis: 1–8% (5%) Trochlear palsy (transient): 1–2% (1%) Dysesthesia/anaesthesia dolorosa (permanent): 0.8–7% (3%)	• Short-lived IV anaesthesia • Selectivity • Long-lasting effect if hypoesthesia of trigger zone vs. difficult procedure, special training required
	Depending on intensity of thermolesion, and consequently degree of sensory loss				
Glycerol neurolysis N = 1310 pts FU: 1–10 y (6.5 y)	42–84% (68%)	18–59% (38.5%)	61.5% (+): none	Herpes zoster eruption: 50% Meningeal reaction: frequent Numbness ± dysesthesia (permanent): 30% Corneal hypoesthesia (permanent): 15% Keratitis: 5%	• Under local anaesthesia • Easy to perform • Low cost vs. No control of glycerol diffusion and effects
Balloon compression N = 1404 pts FU: 1–6 y (4 y)	82–100% (96%)	54.5–91.3% (67%)	33% (+): 0.2% by carotid injury	Numbness (± transient): 39% Masticatory deficit (± transient): 66% Pterygomaxillary fossa hematoma: occasional	• No numbness • No keratitis vs. • General anaesthesia • Balloon sometimes difficult to place inside the Meckel cave
Stereotactic radiosurgery N = 310 pts FU: 2–7 y (5 y)		21.8–88.9% (54%) (number of patients still under medication)	46% (+): none	Trigeminal hypoesthesia: 0–54% (32%) Corneal anaesthesia: none Trigeminal motor deficit: none	• No invasiveness vs. • Delayed effect • Long-term effect uncertain
Microvascular decompression N = 5122 pts FU: 5–15 y (7 y)	80–98% (91.8%)	62–89% (76.5%) high grade (II–III) of compression: 90% low grade (I): 65%	23.4% (arachnoiditis due to surgical exploration (P = 0.04)) (+): 0–1.2% (0.3%) cerebellar infarct	• Numbness: 2–7% (3%) • Hearing/Gait disturbances (permanent) (2.5%) • Facial palsy (permanent): 0–2% (1%) • Trochlear palsy (transient): 0–5% (1%) • Anaesthesia dolorosa (permanent): 1–3% (1.5%) • Cerebellar infarct: 1% • CSF leakage (transient): 2–17% (4%)	• Highest rate of long-term effectiveness • Keyhole surgery • Infrequent side effects vs. • Some severe complications

In our 1800 patients' series, of whom the first 362 had K-M analysis, probability of cure (i.e. no pain and no medication at 15 years of FU), is 74%; noteworthy, pain relief was equally satisfactory in atypical as in typical clinical presentations (Sindou et al., 2006).

Presence of a marked vascular compression at surgery (grade II or III) was correlated with a high success rate at 15 years of FU 79% and 88%, respectively; Conversely when the vessel was in simple contact (grade I), the probability of long-term relief amounted at only 65% (P = 0.001) (Sindou et al., 2007). Importantly, degree of compression can be predicted by imaging with high reliability (P <0.01) (Leal et al., 2010).

Advantages of MVD are its 'conservative' nature and a high rate of long-term relief when a clear-cut NVC is found. Disadvantage is the potential risk of an open surgery.

An illustration of proposed decision-making for TN is given in Figure 79.7.

Radiofrequency thermorhizotomy

Percutaneous radiofrequency thermorhizotomy (RF-ThRh) (Fig. 79.8) was introduced by Sweet as a refined version of the former electrocoagulation of the Gasserian ganglion pioneered by Kirschner in 1933 (Kirschner, 1933; Sweet and Wepsic, 1974). RF-ThRh is performed under short-lived bolus IV anaesthesia (currently with propofol) sequentially repeated as necessary. The needle electrode is driven under fluoroscopy using the *Hartel's route* through the foramen ovale, up to the immediate retrogasserian portion of the trigeminal nerve, namely the Triangular plexus where fibres have a somatotopic organization corresponding to the three trigeminal divisions. The (5 mm ± 2) uninsulated extremity of the electrode should be placed in the fibres corresponding to the pain territory, under X-ray and neurophysiological guidance, the latter based on evoked paraesthesias and muscular responses to electrical stimulation (Sindou, 1999; Tatli and Sindou, 2008). A thermolesion between 65°C and 75°C is performed to achieve a preferential, if not a totally selective analgesic effect. The lesion must not be made in the ganglion itself, but retrogasserian at the triangular plexus level to decrease the risk of trophic ulcerations by destroying the T cells of the ganglion (Sindou and Keravel, 1979). To obtain a marked hypoesthesia without important loss of tactile sensation and cover but not transpass the division(s) involved, an

accurate placement of the electrode and a gradual lesioning process are required, which is demanding and time-consuming, but of paramount importance.

Literature results are summarized in Table 79.1. In all reported series, duration of effect was proportional to the degree of the induced hypoesthesia (Sindou and Keravel, 1979). In our series, recurrence rate after FU ranging from 5 to 25 years was 7%, with the drawback that 95% of the patients had significant hypoesthesia in the pain territory. However, the resulting numbness was well-tolerated in all but 2% of the patients, these 2% suffering disabling dysesthesias (Sindou and Tatli, 2009).

Advantage of RF-ThRh is topographical selectivity. Disadvantage is the difficulty to target the proper fibres and to achieve an optimal degree of hypoesthesia. If excessive, the thermolesion may aggravate the background of burning pain in atypical TN and may also produce keratitis.

Rf-ThRh is particularly useful for patients harbouring classical TN but with precarious general condition or patients with TN due

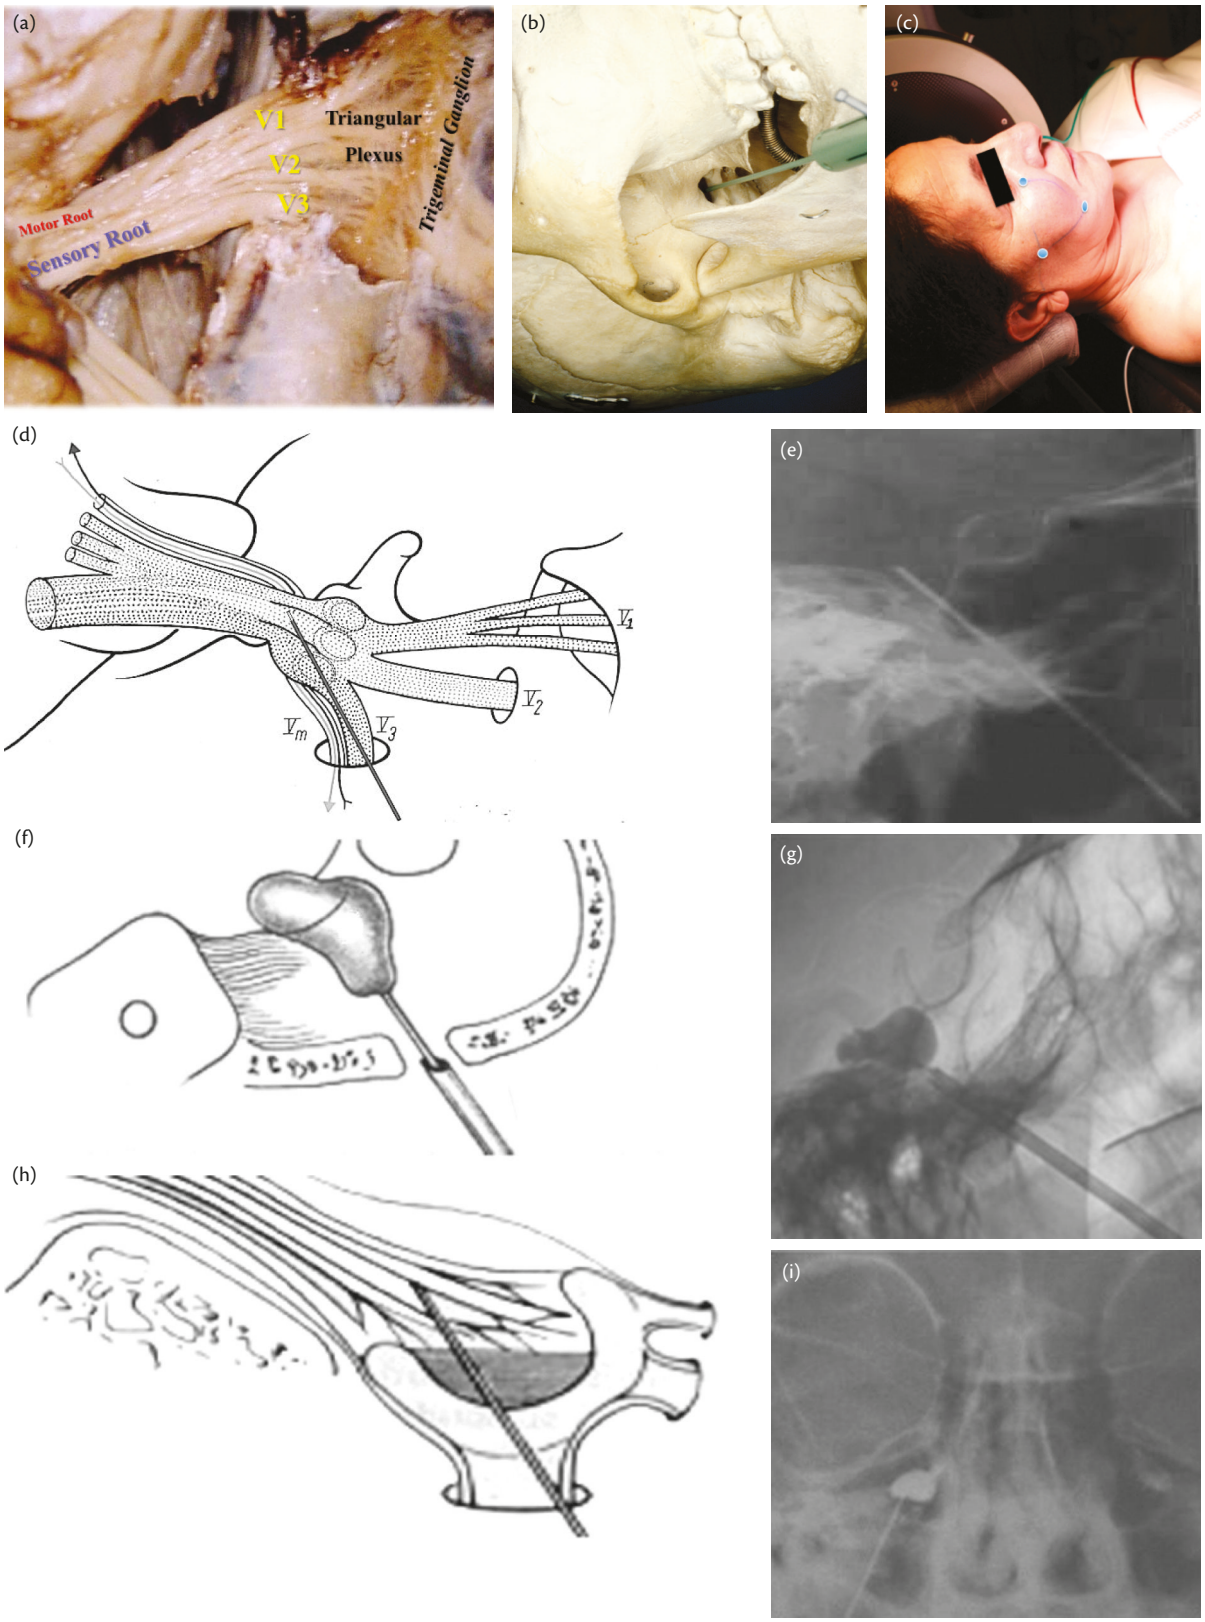

Fig. 79.8 Percutaneous lesioning techniques for tigeminal neuralgia. (A-C); Landmarks and trajectory for Hartel's transforamen ovale route (on right side). The entry point of the needle is on average at ±30mm from the labial commissure)±60mm from the middle of the intercommissural line). The foramen ovale is targeted by aiming (i) in lateral view, at 35mm anterior to the anterior wall of the external auditory meatus (tragus), (ii) in frontal view, the medial border of the pupil, (iii) the depth of the needle is guided by X-ray fluoroscopy to the level of the triangular plexus. (Tatli et al., 2008). Surgery should performed under fluoroscopy to be in accurate location (i.e., intersection of the clivus line and the upper petrous ridge) (Tatli et al., 2008). Wrong (and dangerous) trajectories would be, back to front, to jugular foramen, infrapetrosal carotid segment, carotid at foramen lacerum, orbital apex through the lower orbital fissure, then juxtaclinoidal carotid through the superior orbital fissure. (D-E): Schematic drawing and X-ray control (lateral view) for RF-Thermorhizotomy. Note the fibers from V1 division are located supero-medially, those

to multiple sclerosis (Kanpolat et al., 2001). It may also be applied to patients with secondary TN when the main component is of the paroxysmal and/or the allodynic types.

Balloon compression of gasserian ganglion

Percutaneous balloon compression (Fig. 79.8) was introduced by Mullan in the 1980s (Mullan and Lichtor, 1983). The procedure is performed under general anaesthesia with tracheal intubation and X-ray guidance of a No. 4 Fogarty catheter through the foramen ovale. Balloon should be driven inside the walls of the MC. Appropriate placement is confirmed by the pear-shaped aspect of the balloon inflated with metrizamide. Compression is maintained for approximately five ± 2 minutes according to authors. Bradycardia may happen during compression.

Literature results are summarized in Table 79.1. The method has few side effects with the exception of a high rate of (most often transient) masticatory deficits. Hypoesthesia is generally mild, especially regarding cornea (Keravel et al., 2009).

Disadvantages are effects not topographically specific and a relatively high recurrence rate. As incidence of keratitis is low, main indication is TN with involvement of the V1 territory.

Gasserian ganglion neurolysis with glycerol injection

Percutaneous gasserian ganglion neurolysis (Fig. 79.8), was developed by Håkanson in the 1980s, consists of injection of glycerol into the CSF of the trigeminal cistern, inside the MC (Håkanson, 1981). The procedure is performed under local anaesthesia with metrizamide fluoroscopic control for an accurate placement into the cistern. The technique is easy to perform but control of diffusion of glycerol outside the trigeminal cistern is somewhat hazardous.

Literature results are summarized in Table 79.1. Frequent side effects are Herpes Zoster eruption, paraesthesias and keratitis (Tatli et al., 2008).

Owing to its low cost, the method is widely performed around the world. In addition to potential complications due to its neurotoxicity, disadvantages are lack of predictability in terms of topography of effect and of long-term efficacy.

Stereotactic radiosurgery

The concept of stereotactic radiosurgery (SRS) for treating TN was introduced by Leksell as soon as the 1970s (Leksell, 1971). But the method became popular only in the last decade, when refinements in MRI allowed precise delineation of target. Irradiation is a single dose of 70–90 Gy, delivered with an isocentre at 4 mm. According to Régis's team recommendation, target should be at the retrogasserian cisternal portion of the TR, in the order of 7.5 mm from exit to porus, rather than at the trigeminal root entry zone (TREZ), to minimize brainstem irradiation (Régis et al., 2009) (Fig. 79.9).

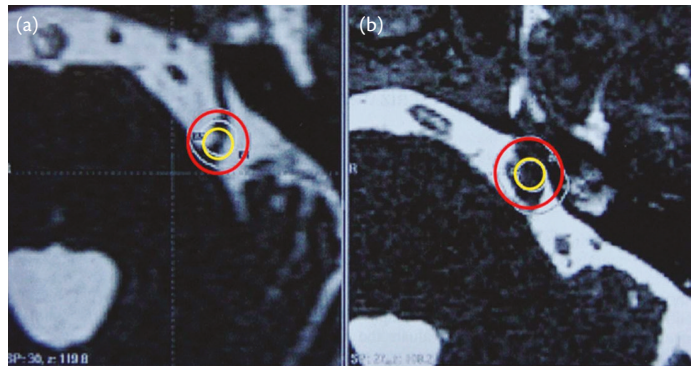

Fig. 79.9 Stereotactic radiosurgery (SRS) targets: this figure shows the two currently used targets with high-resolution T2 sequence. (A) Target at the TREZ; (B) target at the cisternal portion of the root. The target considered the least dangerous is the cisternal target, more distant from brainstem. Yellow circle, 80 Gy isodose curve; red circle, 30 Gy isodose curve.

Literature results are summarized in Table 79.1. Results significantly vary between reports, possibly because of differences in targets and doses. Furthermore, pain relief was diversely estimated among authors; in a number of publications, outcome was classified as satisfactory though patients were maintained on medication. Hypoesthesia together with subsequent numbness and paraesthesias are reported at 0–54% according to series. Although controverted by some authors, general consensus is that obtention of pain relief and its duration depend on the presence and degree of hypoesthesia ($P = 0.02$) (Pollock, 2006; Régis et al., 2016). For that reason, Pollock estimates that SRS for TN should be considered among the lesioning techniques.

Advantages of SRS are low invasiveness and low rate of complications. Disadvantage is the delay in obtaining pain relief, generally several months; however, this inconvenience is not a major problem for most patients with the exception of those referred for unbearable refractory pain.

Decision-making

Complete high-resolution MRI exploration is of extreme practical importance for decision-making as it gives the necessary anatomical bases for indicating the most appropriate procedure. There is a general consensus that MVD be considered as the first surgical option when the patient's conditions are favourable. Percutaneous lesioning techniques or stereotactic radiosurgery are most helpful for patients in whom imaging does not reveal clear-cut vascular compression;

Fig. 79.8 Continued
corresponding to V3 division infero-laterally and those corresponding to V2 division between the two. The uninsulated tip of the electrode should be located in a somatotopic way according to the trigger-zone and pain territory. Location is guided by evoking paresthesia to electrical stimulation of the root while the patient as awake and/or eliciting trigemino-facial reflexes (especially the blink-reflex) in the corresponding facial muscles (Sindou 1999). Then thermolesion is done under brief general anesthesia to provide analgesia (tested by pinprick) without complete loss of tactile sensation of skin and mucosa and decrease in corneal reflex (tested by cottonoid contact). (F-G): Schematic and X-ray control (lateral view) for balloon compression of the Gasserion ganglion and triangular plexus. Note the pear-shaped aspect of the inflated balloon, which testifies of the ideal location inside the Meckel's cave and the trigeminal cistern. (H-I): Schematic drawing and X-ray control (AP view) for Glycerol injection in the trigeminal cistern. An iodine contrast should ensure that needle is located within the trigeminal cistern; then the glycerol solution is injected with patient awake.

they also constitute an effective recourse when patients are in precarious conditions.

Comparison of the various neurosurgical methods available for TN is rather difficult because of heterogeneity between published series. The reasons for this are: heterogeneous patient selection criteria among teams; technical differences in performing surgery; disparities between authors for outcome assessment, as well as for evaluation of side effects and complications; and rarity of long-term studies with Kaplan–Meier analysis.

Vago-glossopharyngeal neuralgia

Glossopharyngeal neuralgia should rather be named vago-glossopharyngeal neuralgia, as pain frequently affects not only the ninth sensory territory of the ninth CN but also the one tributary of the vagus nerve (tenth CN). VGPN is one hundred times less frequent than TN. Definition is clinical; VGPN consists of paroxysmal, transient, severe, sharp pain in the back of the throat, the tonsillar fossa, the base of the tongue, the depth of the ear canal, the area beneath the angle of the mandible. Pain usually lasts seconds to minutes and is often triggered by swallowing, eating, chewing, coughing, yawning, talking, and so on (Headache Classification Committee, 2013). VGPN may be sometimes associated with cardiovascular manifestations, especially syncopes (Chen and Sindou, 2015), and only exceptionally with digestive manifestations (Anthérieu et al., 2016).

Aetiology and pathophysiology

VGPN can be secondarily, be due to extracranial or intracranial tumours, or various other specific pathologies. In the last decade, primary VGPNs were recognized to be most often due to ninth-tenth CN arterial compression, predominantly but not always at REZ, and named, as for TN, classical. High-resolution MR is able to depict compressive vessels with a high sensitivity and specificity, in the same way as for TN (Kawashima et al., 2010; Leal et al., 2010).

Diagnosis

Diagnosis is based on the particular features of the pain. Clinical examination does not reveal any obvious neurological deficit. ENT investigations and MRI rule out diagnoses of extracranial or intracranial tumours, vascular lesions, Chiari malformations, and others. In most patients with classical VGPN, high-resolution MRI shows a compressive elongated artery generally the PICA and/or the VBA.

Surgical management

When medical treatment, based on anticonvulsants as for TN, fails or is not tolerated, surgical treatment should be considered. Percutaneous RF-ThRh that can be performed at the foramen jugularis is rarely indicated for primary VGPN, due to the high risk of creating deficits in the motor territories of the ninth and tenth CNs (Lazorthes and Verdie, 1979; Tew et al., 1982). To be mentioned, Rf-ThRH should be rather reserved to pain of neoplastic origin. Stereotactic radiosurgery (SRS) was recently attempted with some promising results (Dhople et al., 2009; Leveque et al., 2011). For classical VGPN, MVD should be the first option because of its efficacy and its 'conservative' nature (Laha and Jannetta, 1977; Chen and Sindou, 2015).

Approach is a keyhole-type retromastoid craniectomy posterior to the tip of the mastoid process and retrocondylian, so as to follow a laterotonsilar—infraflocculare trajectory, along the cerebellomedullary fissure. Such a trajectory allows to avoid stretching of the eighth nerve and related complications (**Fig. 79.10**). The compressive vessels, generally PICA and/or VBA, lie ventrally to the ninth to the tenth REZ at adjacent brainstem. For effective decompression, the covering arachnoid membranes that are frequently thickened and adhesive to the rootlets should be widely opened and excised.

Results

Literature results have been reviewed and detailed elsewhere (Chen and Sindou, 2015). In brief the review, which included 28 publications totalizing 515 cases, shows that MVD achieved total relief in 50% to 100% of the patients according to authors, with acceptable rates of side effects or complications. In our series of 36 MVD for VGPN with a FU of more than 2 years, complete pain relief was achieved in 94.4% of the patients. There was no mortality, no general morbidity, and no wound complications. Neurological deficits consisted of some degree of (permanent) dysphonia and dysphagia in two patients.

According to recent literature, MVD proves to be an efficacious and relatively safe procedure for primary VGPN. SRS that might be promising needs more long-term evaluation to be included in the therapeutic armamentarium. Percutaneous RF-ThRh should be reserved for pain from neoplastic origin with already neurological deficits.

Tinnitus and vertigo

Tinnitus

Tinnitus is a very common symptom, mostly due to auditory deafferentation after inner ear, peripheral or central nervous system damages that result in neuronal hyperactivity and/or functional reorganization within central auditory structures (Møller, 2007; Londero et al., 2009). Origin from vascular compression is controversial; close relationships of cerebellar arterial loops with the eighth nerve in CPA cistern or the internal auditory canal are very common findings in asymptomatic patients. However, under very specific conditions, patients affected with handicapping unilateral tinnitus, with no identifiable cause other than an image of neurovascular conflict, may be candidates for eighth CN MVD (De Ridder et al., 2012; Mathiesen and Brantberg, 2015).

Criteria are both anatomical: a clear-cut arterial loop on MRI compressing the nerve at REZ or distorting its trajectory within the cistern or the auditory canal, and physiological: an increase in latency of peaks III and V at brainstem auditory evoked potentials (BAEPs) recordings. An ipsilateral vestibular hyporeflexia can be also an argument.

Reports, which are few, coincide on the fact that in spite of strict selection outcomes remain uncertain, especially when duration of tinnitus prior to surgery has been prolonged.

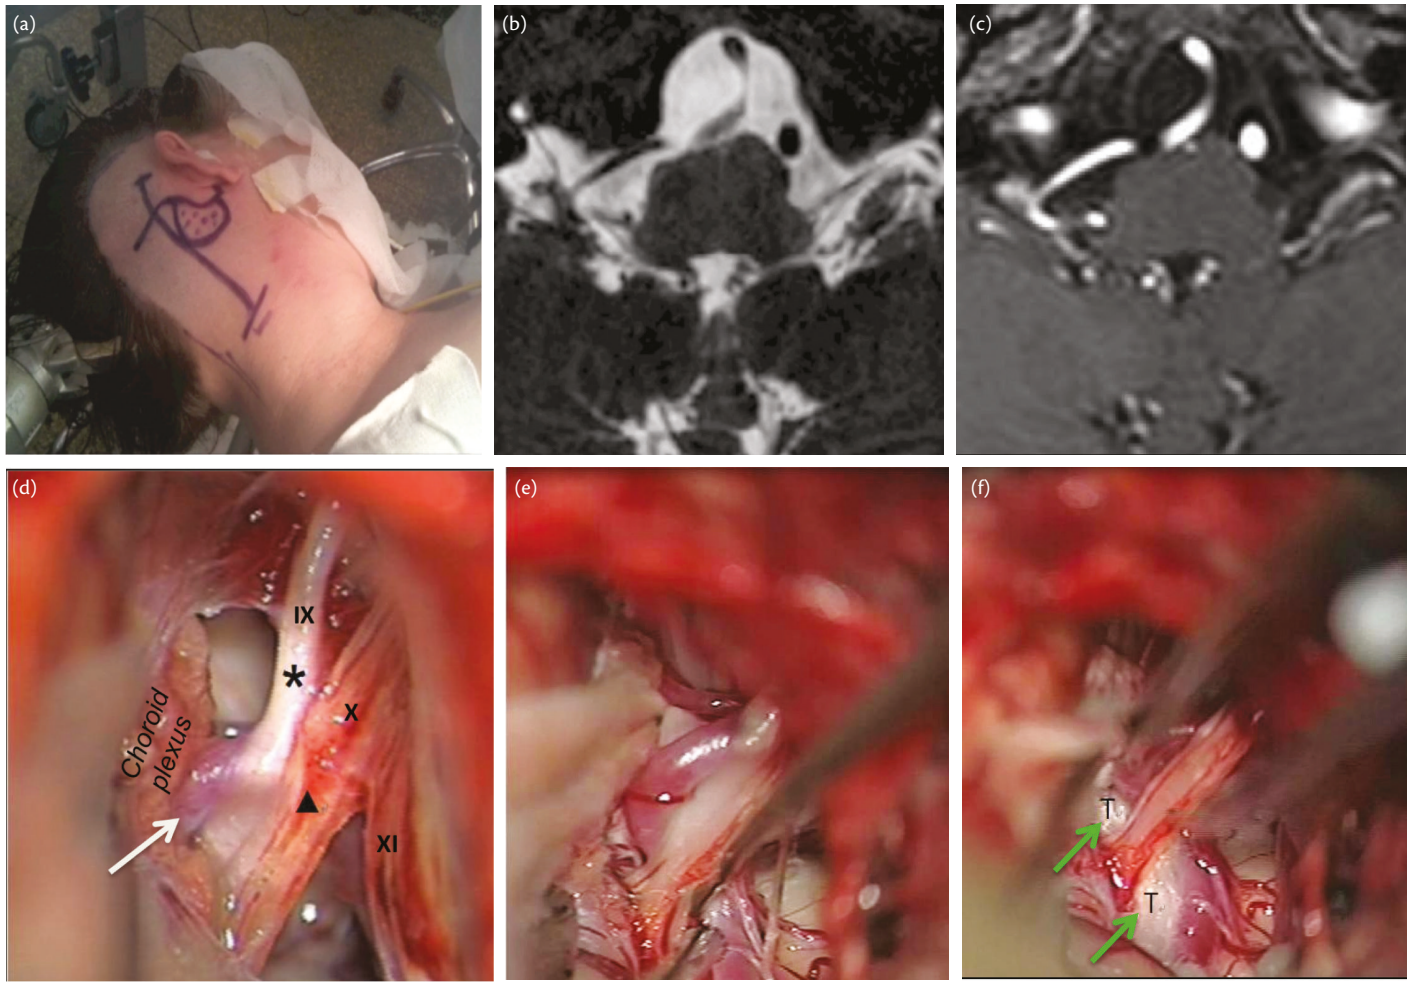

Fig. 79.10 Vasoglossopharyngeal neuralgia (on right side) due to neurovascular conflict from posterior inferior cerebellar artery (PICA), as seen on MRI with high-resolution T2 (B) and T1 + gadolinium (C) sequences. Landmarks of keyhole (retromastoid, retrocondylar, and retrosigmoid) approach for vagal and glossopharyngeal microvascular decompression (A). Infrafloccular microsurgical approach on the right side. The offending PICA is ventral to the REZ of the ninth (asterisk) and the tenth (triangle) nerves. Note the atrophic and greyish aspect of the ninth and tenth rootlets testifying of focal demyelination (D). The compressive PICA (arrow) is detached after dissection and freeing of the rootlets from arachnoid adhesions (E). The Teflon felt bundle (T) is placed so that the artery is maintained apart from REZ of ninth and tenth rootlets (F).

Vertigo

Prevalence of vestibular paroxysmia due to NVC is difficult to evaluate among the various and frequent vestibular disorders (Tilikete and Vighetto, 2009). Estimation is around 4% according to a review by Hüfner (Hüfner et al., 2008). 'Disabling positional vertigo (DPV)', as characterized by Jannetta and Møller's group, is considered as the most evocative clinical presentation of this aetiology (Jannetta et al., 1984; Møller et al., 1986).

Diagnosis and side of vascular compression are not easy to ascertain in the absence of associated auditory symptoms and signs. As a matter of fact, vascular loops in contact with the eighth CN is a common finding in many asymptomatic individuals. Unlike auditory symptoms, abnormalities found at vestibular investigations are neither specific nor reliable regarding the side or the endo- or retro-labyrinthic topography of the pathology. In ocular movement recordings, the rapid component of the nystagmus, whether spontaneous or positional, may be directed either to the affected or the normal side, indicating hyper- or hypo-excitability of the vestibular system, respectively. The same applies to the caloric test, the responses being diminished or increased according to whether the affected vestibular system is hypo- or hyper-excitable. Thus, in the absence of obvious unilateral abnormalities on the auditory investigations, namely an increase in latency of peak III and V on BEAP recordings, vestibular tests cannot be relied upon to confirm diagnosis, as well as to determine side and level of NVC.

Surgery, of any type, should be considered only for incapacitating vertigo, of a degree of 5–6 on the functional scale of the Committee on Hearing and Equilibrium (Committee on Hearing and Equilibrium guidelines for the diagnosis and evaluation of therapy in Menière's disease, 1995). When there are sufficiently solid arguments for vascular compression, MVD is the best choice because of its conservative nature (Hüfner et al., 2008). The responsible compression may be exerted by AICA or PICA at REZ or by an AICA loop in cistern or internal auditory canal. A lesioning procedure, such as vestibular neurotomy, would be only justified if preservation of auditory function is considered to be useless, that is, when tonal audiometry is less than 50 dB and vocal threshold inferior to 50% (class C–D of the Classification of the American Academy of Otorhinolaryngology

and Head and Neck Surgery) (AAOHNS) (Møller et al., 1986), (Committee on Hearing and Equilibrium guidelines for the diagnosis and evaluation of therapy in Menière's disease, 1995; Lacombe, 2009). Of course, auditory function in the contralateral side has to be verified prior to decision.

In largest published series MVD of the eighth nerve was reported as at least partially effective in approximately three-quarters of the patients in the series of Møller and Ryu (Møller et al., 1993; Ryu et al., 1998). Weakness of these reports is that patients were not systematically assessed with auditory and vestibular tests; also, functional tests were not applied. In both publications disabling complications were rare; complete hearing loss was reported at only 2% of the operated patients. However, a certain decrease in hearing was noticed in most patients.

Motor ocular syndromes

Neurogenic hyperactivity may provoke episodic spasms of one or several extraocular muscles, with a variety of clinically observable manifestations, including ocular neuromyotonia, superior oblique myokymias, ocular motor synkineses, cyclic spasms, and so on, all resulting in diplopia. Pathophysiology varies and may result from a number of diseases (Vighetto and Tilikete, 2009). Not always understood, mechanisms usually involve central rearrangement of neuronal activity in the attained nuclei. However, a proportion of apparently idiopathic cases—rather rare (three cases affecting the fourth CN and one case the third CN)—were reported in relation with a neurovascular compression (Samii et al., 1998; Mikami et al., 2005; Inoue et al., 2012; Fam et al., 2014).

To be noted, several other cases reported as NVC and treated so-called by MVD were in fact palsies by ectatic arteries.

Complex dystonic/painful manifestations

Occasionally, patients may be referred harbouring complex dystonic/painful manifestations in the face, of somewhat mysterious origin, and considered possibly related to psychogenic mechanisms. Visualization of an image of possible NVC may incite to consider MVD. As an illustration we treated one such female patient suffering from painful unilateral dystonic paroxysms of the masticatory and facial muscles on one side, accompanied with anarchic ocular revulsions, and time to time followed by falls. Symptoms were totally relieved after MVD from an AICA loop deeply embedded inside the pontomedullary junction.

Neurogenic blood hypertension

Among the hypothetic aetiologies of so-called essential hypertension (HT), one mechanism may be neurogenic dysfunction due to vascular compression of the ventrolateral (VL) aspect of medulla. Since this hypothesis was applied to humans by Jannetta and his group in the late 1970s, only few studies either clinical or experimental in baboons have been reported in the literature, although such a neurogenic mechanism might potentially concern a large number of individuals (Jannetta and Gendell, 1979; Jannetta et al., 1985; Geiger et al., 1998; Levy et al., 2001; Naraghi et al., 2001).

Surgical data

In their first clinical report Jannetta and Gendell observed a higher rate of neurovascular compression of the VL medulla predominantly on the left side in patients affected with TN or HFS when hypertension was associated (Jannetta and Gendell, 1979). To be noted, the predominant left-sided lateralization is concordant with the prevalence of left ninth to tenth nerve complex in conveying the afferences from the baroreceptors of the (left-sided) cardiac atrium.

Ever since only two surgical studies were published: one, retrospective, by Jannetta et al. with 53 patients and the other prospective, by Geiger et al. with 36 patients (Jannetta et al., 1985; Geiger et al., 1998). In both series MVD improved uncontrolled HT in 84% and 80%, respectively.

Our contribution to the field was assessment, in a prospective study, of the effects obtained on blood pressure (BP) by MVD of the ninth to the tenth REZ and adjacent VL medulla, in addition to MVD of the facial REZ, in a group of 48 patients operated on for their HFS and in whom an apparently essential HT was present (Sindou et al., 2015). In summary all enrolled patients except one had a HT of at least WHO grade I, and 18 of them an unstable form, despite appropriate medical treatment. In all, the conflicting vessel(s) found exerted compression ventrally at the REZ of the ninth to tenth CNs and at adjacent VL medulla. After MVD, at latest FU (2 to 16 years, 7 years on average), BP was found to be normalized in 28, 14 of which without the need for any antihypertensive treatment (P <0.0001). Also, at the latest FU, BP remained unstable in only 8 of the 18 patients who had unstable BP prior to MVD (P <0.02). These findings indirectly plead for an efficacy of MVD in the treatment of refractory, apparently essential, HT (**Fig. 79.11**). Regarding the side, of the 30 patients with left-sided compression 17 had BP normalized (11 of them with no need for medications), and of the 18 with right-sided compression, 11 had a normalized BP (three of them with no need for medications); however, difference was not statistically significant.

MRI findings on HT

Because not all patients with essential HT, which failed to be controlled by medications, cannot be eligible for surgery, selection should be primarily based on MRI findings, provided sufficient reliability. Most publications in literature report a higher rate of images with vascular contact/compression (vc/c) at the VL medulla in the group of patients with essential HT, compared to the group with normal BP (Sindou, 2015). Left-sided vc/c had higher rate than right-sided vc/c. However, statistical significance was absent in the prospective studies (P = 0.178) as opposed to the retrospective ones (P = 0.001).

The difficulty to discriminate whether an elongated arterial loop at the VL medulla and adjacent ninth to tenth REZ is the cause or the consequence of the increased BP is major limitation for MRI-based decision-making. Comparison of images between patients with apparent primary HT and secondary HT shows that in the latter group (secondary HT), rate of NVC at brainstem was lower than in the group with primary HT, a finding however that did not reach statistical significance.

Discussion/Conclusion

Arguments suggesting that vascular compression of VL medulla at level of ninth to the tenth REZ seem convincing enough to

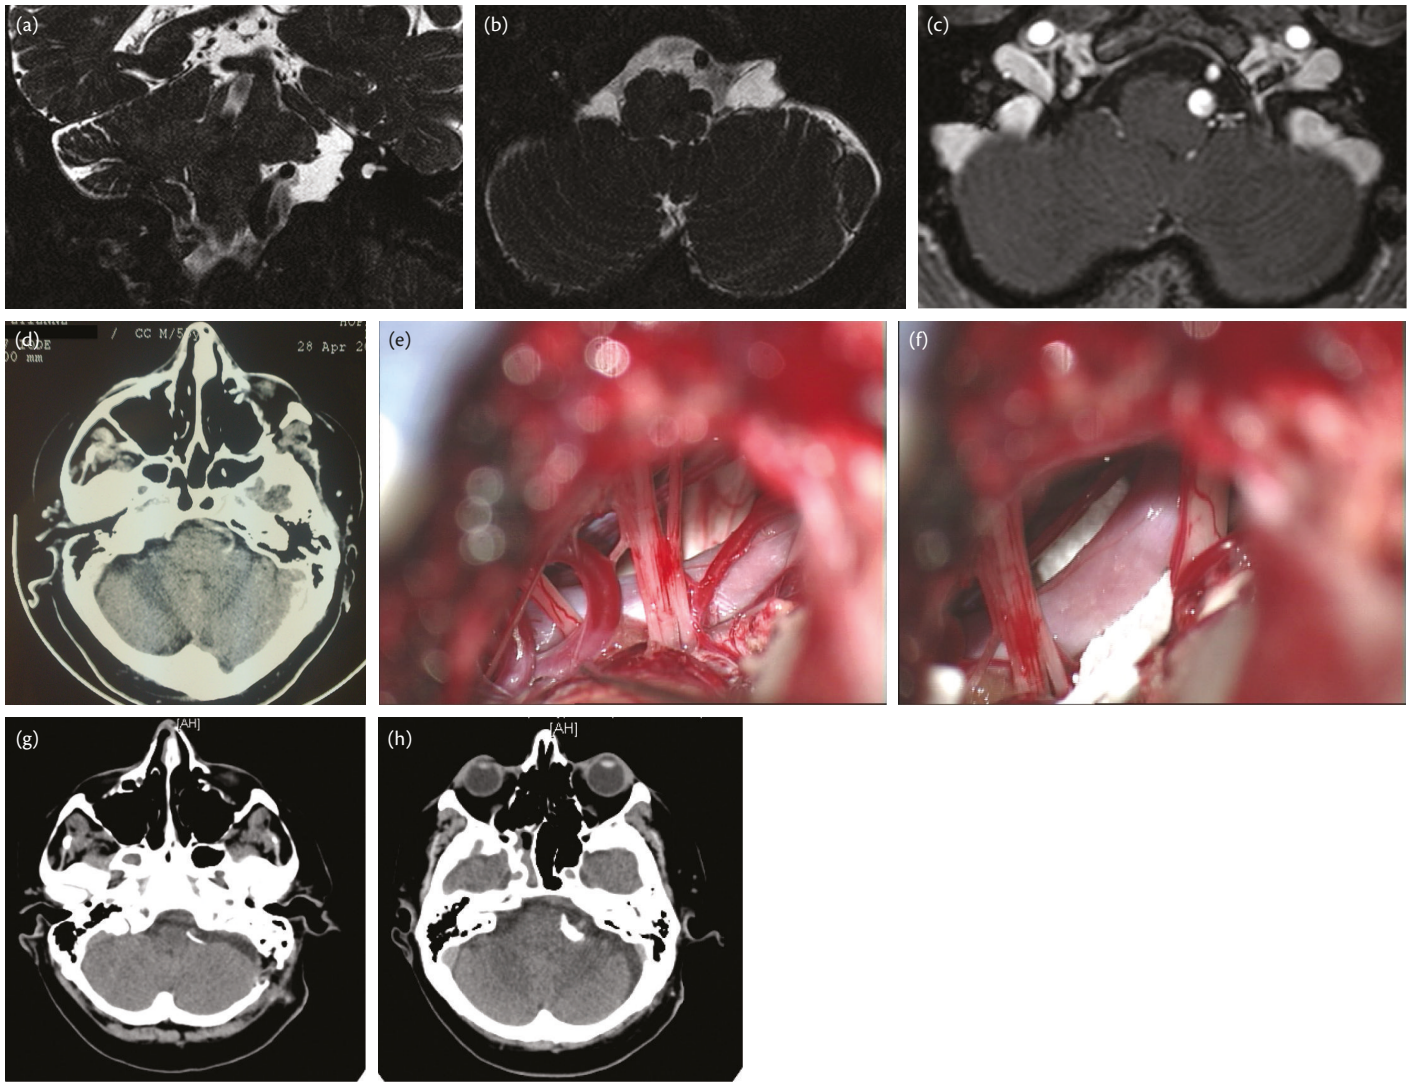

Fig. 79.11 Blood hypertension, likely from neurogenic origin due to vascular compression of ventrolateral brainstem and REZ of ninth and tenth CNs (on left side).
Imaging: Compression of VL medulla, on the left side, by a megadolicho-vertebrobasilar artery (VBA), on T2-coronal (A), T2- (B), and T1-gadolinium (C) axial views. On computed tomography (CT) axial view (D), location of megadolicho VBA is on left side.
Operative views: On the left side, at cerebellomedullary fissure, compression of VL medulla, ventral to tenth and ninth REZ and rootlets. (E) Brainstem and rootlets decompressed after interposed piece of (semi-rigid) Teflon (F). Note location of Teflon plate (hyperdense) on post-op CT axial views (G, H).

consider vascular decompression as a possible measure for the treatment of apparently essential HT likely to be of neurogenic origin (Sindou, 2015). The main problem remains patient selection, even when MRI reveals images of megalodolicho-artery(ies) likely to compress brainstem. However, it could be justified to consider decompressive surgery in the patients in whom in spite of a well-conducted medical treatment BP remains high, unstable, and thus life-threatening.

General conclusion–epilogue

Over the last decades important advances were made to identify and treat a number of so-called CN vascular compression syndromes at the origin of hyperactive functional disorders.

Indication of microvascular decompression (MVD), that must remain considered on rigorous clinical, bases may largely benefit from a battery of for neurophysiological tests and from the recently developed high-resolution imaging.

However, not all operated patients are cured. Undoubtedly, several of these (puzzling) disorders—sometimes considered from more or less psychogenic origin—arise from multifactorial mechanisms. A large amount of work still remains to be done to better understand mechanisms, accurately select patients, and improve efficacy and safety of surgical techniques.

Neurosurgical interventions for psychiatric disorders

Chris Bervoets, Bart Nuttin, and Loes Gabriëls

Introduction

Psychiatric disorders are among the most prevalent illnesses worldwide and up to one-third of the general population suffers from an anxiety disorder or a depressive disorder (Kessler et al., 2005a; 2005b). Established treatments for psychiatric disorders include pharmacotherapy and psychotherapy. Various non-pharmacological, neuromodulatory strategies comprising electroconvulsive therapy, magnetic seizure therapy, vagal nerve stimulation, repetitive transcranial magnetic stimulation, and deep brain stimulation of psychiatric disorders have been investigated. Although these treatments are at various stages of clinical development, they represent a new frontier in expanding the treatment options available for individuals with psychiatric disorders, as well as contributing to a better understanding of the neurobiology for these disorders. With regard to the understanding of neurobiological aspects, there are well-validated animal models for most of the psychiatric disorders, and further progress in this field is made (e.g. van Kuyck et al., 2007). In combination with prior lesioning experience from published case reports and case series, and with additional information of neuroimaging, target selection is robustly scientifically underpinned. In addition, functional neuroimaging studies and physiological findings while using DBS in the treatment of other conditions have led to investigation of additional targets.

Reports on neurosurgical treatments for psychiatric disorders date back to 1935, with Egas Moniz and Almeida Lima reporting on a series of frontal leucotomies (later renamed 'frontal lobotomy' by Walter Freeman and James Watts) and using the term 'psychosurgery' for the first time (Feldman and Goodrich, 2001). The development of stereotactic techniques by Spiegel and Wycis in the 1940s, followed by the introduction of computed tomography and magnetic resonance imaging, provided an opportunity to perform more accurately upon lesions in the brain. Together with the growing knowledge on the link between specific brain regions and different aspects of behaviour, the development of a standardized nosological system in psychiatry, and the growing use of rating scales to evaluate treatment outcomes, this stereotactic surgery gained ground in the treatment of psychiatric disorders (Larson, 2008). Nevertheless, non-reversible lesioning of brain regions in order to alleviate severe psychiatric symptoms have often been associated with negative connotations, making lesioning procedures less acceptable as a treatment option. The development of deep brain stimulation (DBS) in the 1990s has led to renewed interest in the surgical treatment of psychiatric disorders. Building upon the fact that DBS is a reversible technique, adjustable trough manipulation of contact choice and stimulation parameters without lesioning the targeted neurocircuitry, DBS is perceived as having advantage over lesional surgery by patients. Moreover, due to the possibility to turn stimulation off, more rigorous clinical trials can be conducted in controlled conditions and with blinding of the evaluator to the stimulus condition. DBS has offered hope for patients with severe and incapacitating psychiatric disorders, although the need for large-scale studies with long-term follow-up remains paramount (Gabriëls, 2010; Luyten et al., 2016). In this chapter we will (i) provide the pathophysiological basis of psychiatric disorders with relevance to neurosurgical intervention; (ii) describe the pre- and postoperative management of the patient as well as the surgical techniques; and (iii) discuss methodological problems that hamper future development of this treatment technique in psychiatry.

Preoperative management of the patient

Patient selection

Only patients aged over 18, with a documented, otherwise treatment refractory, severe, chronic, disabling psychiatric disorder should be considered for surgical intervention. The potential benefit from an intervention must be balanced against the risks imposed by surgery (Gabriëls, 2010). Obsessive-compulsive disorder, Tourette's syndrome, and major depressive disorder might benefit from surgical intervention. In those patients, a history of personality disorder, active substance abuse or other Axis II symptomatology are (relative) contraindications for surgery. A critical issue in patient selection remains the development of solid criteria for severity, chronicity, disability, and treatment refractoriness. Severity is measured using validated clinical research instruments corresponding

to specific indicators such as a Yale-Brown Obsessive-Compulsive Scale (YBOCS) score of more than 30 for OCD or a Montgomery-Åsberg Depression Rating Scale (MADRS) of more than 30 in major depression. Disability is commonly assessed by a Global Assessment of Function (GAF) score of less than 50. Treatment refractoriness needs to be documented by the treating psychiatrist describing all appropriate treatment (specifying dose and treatment duration) according to current published guidelines (Bandelow et al., 2008). Moreover, the psychiatrist needs to provide ongoing commitment to the patient and the evaluation process, and needs to agree to take responsibility for postoperative (non-DBS related) management. The patient and their family must also agree to fully participate. It is advisable to include a family member or close relative in the evaluation process.

Presurgical screening

As a next step, a second opinion by another psychiatrist well acquainted with the disorder can be required (e.g. for surgical treatment of OCD in Belgium) and added to the application file. In Belgium, an experienced, multidisciplinary group of psychiatrists, neurosurgeons, in the presence of an ethicist conducts a thorough review of the medical records. A brain MRI is added to the evaluation, as well neuropsychological testing. Moreover, the requirements for informed consent must be fulfilled.

Surgical technique

Lesional surgery

Four procedures, anterior cingulotomy, subcaudate tractotomy, limbic leucotomy, and anterior capsulotomy, are considered safe and effective for OCD (Jenike, 1998). All procedures are usually performed bilaterally and under stereotactic conditions to allow for precise lesioning of target structures. The anterior cingulum was considered an appropriate target for surgical intervention (Fulton, 1951) in patients with intractable pain and concurrent mixed anxiety-depressive states. Currently, the surgical indications are treatment refractory major depressive disorder, chronic anxiety states, or OCD. Subcaudate tractotomy was introduced in 1964 (Knight, 1964; Knight, 1969) as one of the first attempts to restrict the size of the surgical lesion and therefore minimize the side effects seen with standard prefrontal lobotomy. The aim was to interrupt white matter tracts between orbital cortex and subcortical structures by placing a lesion in the region of the substantia innominata just below the head of the caudate nucleus. Surgical indications included major depressive illness, obsessive-compulsive disorder, and anxiety states. Limbic leucotomy (Kelley et al., 1973) combines subcaudate tractotomy with anterior cingulotomy. This procedure was designed to disconnect orbital-frontal-thalamic pathways with the former lesion and interrupt an important portion of Papez's circuit with the latter. Indications for surgical intervention included obsessional neurosis, anxiety states, depression, and a variety of other psychiatric diagnoses. The aim in anterior capsulotomy (Talairach et al., 1949) is to interrupt fronto-thalamic connections in the anterior limb of the internal capsule where they pass between the head of the caudate nucleus and the putamen. Clinical indications for capsulotomy include depression, chronic anxiety states, and obsessional neurosis.

Deep brain stimulation (DBS)

DBS produces an enduring electrical modulation of targeted deep subcortical brain structures. The lead placement depends on the condition being treated and implantation is done via burr holes in the skull using neuroimaging guided stereotactic neurosurgical techniques. Each lead consists of an electrode array containing usually four electrode contacts spanning 10–20 mm, depending on the lead type. After implantation, the leads are connected via subcutaneous extension wires to one or two subcutaneously implanted battery-operated pulse generators (IPG). The IPG is typically implanted in the subclavicular or abdominal region. Stimulation parameters (contacts used, frequency, pulse width, amplitude) are non-invasively adjusted via a physician-operated patient programmer. Clinically used parameter settings are typically in the range of 60–130 Hz, 60–450 microseconds pulse width, and 2–10 volts, either in monopolar or bipolar stimulation mode (Holtzheimer and Mayberg, 2011). Although DBS is perceived as having an advantage over lesioning procedures, it still is associated with serious risks as intracranial haemorrhage and infection and also complications associated with anaesthesia (Luyten et al., 2016). Moreover, fractures of the implanted lead or extension wire, compliance issues, and the need for frequent IPG replacements due to end of life of the battery are disadvantages that are observed with the use of DBS (Nuttin et al., 2003; Visser-Vandewalle et al., 2003; Abelson et al., 2005; Houeto et al., 2005; Machado et al., 2005; Mayberg et al., 2005). The first DBS targets for OCD were the internal capsule (with its ventral portion referred to as ventral capsule, VC, with inclusion of the bed nucleus of the stria terminalis, BST) and the ventral striatum, or VS (sometimes referred to as including the nucleus accumbens, NAcc). This selection was based on former stereotactic lesioning procedures for the same disorder (Jenike, 1998; Lippitz et al., 1999; Dougherty et al., 2002; Greenberg et al., 2003; Sturm et al., 2003). Our group reported on the use of DBS in the anterior limb of the internal capsule (Nuttin et al., 1999; Nuttin et al., 2003) and BST (Luyten et al., 2016). It is of relevance to point out that a DBS lead spanning this region is capable of influencing any of the aforementioned structures, depending on lead geometry and stimulation parameter settings (Larson, 2008). After the serendipitous finding of alleviation of OCD symptoms with stimulation of specific subdivisions of the subthalamic nucleus in patients who suffered from parkinsonism and OCD, efforts were directed to this node in the cortico-striato-thalamo-cortical circuitry. Case studies report on electrical stimulation for psychiatric disorders in different other targets, for example, in the inferior thalamic peduncle and the internal globus pallidus (GPi).

Postoperative management of the patient

In the phase of postoperative management of the patient, the neurosurgical team should work in close communication with the psychiatric team. As neurosurgery is considered a last resort treatment for patients with chronic and severe psychiatric symptoms, the postoperative psychological and emotional guidance of the patient and the family are of utmost importance. Often, early and dramatic changes in primary symptoms are noted in the patient, with impact on the whole system of surrounding close thirds. It requires counselling and time to find a new equilibrium within the family

or relation. Moreover, optimization of stimulation parameters is a complex and lengthy procedure and requires a supportive attitude from the psychiatrist and family. Moreover, parameter adjustment is best kept under the responsibility of the same physician to allow for intraindividual observation of stimulation related changes in patient's attitude and behaviour.

Future questions

Better understanding of the neurobiology of emotion through basic research may lead to better target selection and more accurate implantation. Combined with findings from further research in non-invasive techniques (e.g. transcranial magnetic stimulation, transcranial direct current stimulation) a new field of research in neuromodulation methods is currently expanding for the treatment refractory psychiatric patients. These techniques have the advantage of allowing double-blind placebo-controlled trials. This was not possible with the former lesioning procedures because of their irreversible and invasive nature. Due to this progress in scientific methodology currently used, an evidence-based statement on safety and efficacy of neurosurgical procedures for treatment refractory psychiatric disorders under investigation becomes possible. Moreover, the use of the invasive procedures is tightly linked with high standard ethical and clinical review boards.

However, we should remain cautious with regard to target selection. In DBS a multitude of targets is explored with growing methodological precision for the same psychiatric indication, and the same target is used for different psychiatric disorders. Secondly, stimulation parameters have an impact on the efficacy of DBS in a patient. At this moment we lack efficient algorithms for optimal parameter selection. Kuncel calculated that above the multiple possible anatomical targets 12 964 combinations of pulse width, frequency, and voltage and 65 combinations of electrode geometry were available within a recommended charge density limit for a given IPG (Kuncel and Grill, 2004). Maybe progress in this field can be made when mathematical models of tissue characteristics and network connectivity maps (built from diffusion tensor imaging) of the target are available to guide the clinician in selecting, improving, and optimizing stimulation parameters in individual patients (Astrom et al., 2009). Lastly, with the emerging research of non-invasive neuromodulation such as TMS, exploration of clinical efficacy of TMS should be compared to results of DBS. This will help to position both invasive and non-invasive neuromodulation in future treatment algorithms.

Classification of seizures and epilepsy

Andrew McEvoy, Tim Wehner, and Victoria Wykes

Introduction

Epileptic seizures are frequently seen as either a presenting symptom or a comorbidity of intracranial pathology encountered by neurosurgeons. The following chapter discusses the current practical definition of epilepsy proposed by the International League against Epilepsy (ILAE) in 2014, and provides an overview of seizure manifestations, reviews two common epilepsy aetiologies amenable to surgical treatment: focal cortical dysplasia and hippocampal sclerosis, and provides an overview of the limbic system anatomy.

An epileptic seizure is a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain (Fisher et al., 2005). Electrographic seizures without any clinical correlate are termed 'subclinical seizures'. Clinical seizure symptoms may be divided into obvious behavioural manifestations ('positive symptoms', e.g. involuntary movements such as clonic jerks), changes in the patient's subjective experience of them self and their surroundings (aura), and impairment of cerebral functions compared to the patient's baseline ('negative symptoms'). In particular, cognitive changes as a seizure manifestation may be subtle and only apparent if the patient is adequately assessed for these. An epileptic seizure is foremost a symptom and may indicate an acute medical or neurological illness (i.e. a provoked seizure). Epilepsy has been traditionally defined as the recurrence of unprovoked seizures. To account for epidemiologic data on risk stratification after first unprovoked epileptic seizures, and to include rare clinical scenarios of similar underlying pathophysiology, the ILAE has recently proposed a practical definition of epilepsy (Fisher et al., 2014; see also **Box 81.1**). Of these, scenario 1 is by far the most common in neurosurgical practice. This definition includes an element of risk stratification. Somewhat arbitrarily, a person is thought to have epilepsy after a single unprovoked epileptic seizure if they have a 60% chance of recurrence risk over the next 10 years without treatment.

The following clinical scenarios illustrate the concepts of provoked seizures and epilepsy.

1. 'Febrile seizures in infancy'—up to 5% of children under the age of 5 years have a convulsive seizure in the setting of a febrile illness. These are considered provoked epileptic seizures that do not constitute epilepsy (even though the recurrence risk with further febrile illnesses is 40%).
2. A person with an acute central nervous system (CNS) pathology such as meningitis or encephalitis, subdural hematoma, ischaemic stroke, or traumatic brain injury may have an epileptic seizure at the onset or in the early phase (arbitrarily defined as the first seven days) of the acute illness. These seizures are considered provoked epileptic seizures. Since all cortical pathologies increase the risk for epilepsy, these patients may be at risk of developing epilepsy, however, one would not consider them to have epilepsy during the acute phase of the illness. A person who has a seizure more than 1 week after an acute CNS insult (unprovoked epileptic seizure) is thought to carry a more than 60% chance of experiencing further seizures and would thus be considered to have epilepsy even after their first seizure.
3. A person with a focal motor seizure affecting the left arm who is found to have a meningioma along the right frontal convexity meets the practical ILAE definition of epilepsy even after their first seizure. This is because the presence of the meningioma increases the risk of further seizures in this patient.

Focal and generalized seizures

Generalized seizures are conceptualized as originating at some point within and rapidly engaging bilaterally distributed networks (Berg et al., 2010).

Focal seizures are conceptualized as originating at some point within networks limited to one hemisphere (Berg et al., 2010). It may stay confined to this area, or evolve further within the same hemisphere or both hemispheres. A focal seizure may thus evolve into a bilateral convulsive seizure ('secondarily generalized seizure').

Seizure types have been traditionally classified under these two subcategories. However, the semiology (i.e. clinical manifestations) of a seizure is not specific for either subcategory. For example, atonic seizures, clonic seizures, tonic seizures, and myoclonic jerks may be generalized or focal in origin (and thus only affect one or unilateral extremities). The clinical manifestation of a typical absence seizure (brief interruption of consciousness with immediate full recovery) may be emulated by a focal seizure (e.g. arising from the frontal pole). Conversely, it is increasingly recognized that generalized tonic-clonic seizures may have focal semiological features. Epileptic

Box 81.1 Conceptual definitions of seizure and epilepsy and practical definition of epilepsy

An epileptic seizure is a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain.

Epilepsy is a disease of the brain defined by any of the following conditions:

1. At least two unprovoked (or reflex) seizures occurring more than 24 h apart
2. One unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (60% or more) after two unprovoked seizures, over the next 10 years
3. Diagnosis of an epilepsy syndrome

b) Reproduced with permission from Samuel Wiebe, Masako Watanabe, Torbjörn Tomson, et al., ILAE Official Report: A practical clinical definition of epilepsy, *Epilepsia*, Volume 55, Issue 4, pp. 475–82, Copyright © 2014 John Wiley and Sons.

spasms, a common seizure type in infants with tuberous sclerosis or other gross brain pathology, have features of both generalized and focal seizures (bihemispheric EEG involvement from the onset, but in some cases amenable to surgical cure by resective neurosurgery restricted to one hemisphere (Chugani et al., 2015). The semiologic seizure classification proposed by Lüders et al. (1998), and increasingly utilized by epilepsy surgery centres around the world, classifies seizures exclusively on their phenomenology.

The vast majority of seizures and epilepsies encountered by the neurosurgeons are (primarily) focal seizures. Traditionally, these are divided into those with preserved awareness ('simple partial seizures') and those with impaired awareness ('complex partial seizures'). While alteration of consciousness often defines the morbidity of seizures (with implications for driving, employment, and leisure activities), it is not possible to infer reliably from the patient's account or their behaviour whether consciousness was preserved or impaired during a seizure.

Any seizure may cause alterations in these four domains: (1) subjective experience of self and environment; (2) awareness, cognition, and memory formation; (3) autonomic alterations; and (4) motor and behavioural manifestations. Whereas the latter are usually obvious, registration of changes in the first three domains depends on the way a person is assessed during and after a seizure. Some but not all semiological features of seizures can be reproduced during direct electrocortical stimulation of specific brain areas. These include elementary or complex visual hallucinations or blindness in the primary visual cortex, and somatosensory hallucinations (tingling) in the primary sensory cortex. Other subjective manifestations are very typical for seizures arising in the limbic system, in particular in the amygdalo-hippocampal complex of the mesial temporal lobe. These include sensations of familiarity ('déjà vu', 'déjà entendu') or alienation ('jamais vu', 'jamais entendu'), a rising sensation in the epigastrium and/or chest, and (usually unpleasant) olfactory and gustatory hallucinations, the latter often with a 'metallic' character. Some motor manifestations can be consistently reproduced during electrocortical stimulation as well. These are myoclonic or tonic contractions of the contralateral face and distal extremities in the primary motor cortex of the precentral gyrus, proximal tonic contractions in the supplementary sensorimotor area in the mesial aspect of the superior frontal gyrus, and contralateral eye and head deviation in the frontal eye fields. So-called negative motor phenomena (i.e. interruption or cessation of a movement or speech) can be reproduced during cortical stimulation of premotor areas, usually just anterior to the primary motor cortex. Observation of these symptoms and signs during a seizure suggests that the respective cortical areas are involved at a given time during the seizure. This is especially relevant since seizures with purely subjective symptoms (i.e. epileptic auras) or focal clonic or tonic contractions are often not detectable on scalp EEG. This is because the amount of cortex that needs to be ictally activated to generate these symptoms is usually smaller than the area of cortex required to generate an ictal pattern on scalp EEG. Patients with focal motor seizures of the face, arm, or leg may indeed have a completely normal ictal and interictal EEG.

On the other hand, complex movements (automatisms) such as lip smacking, chewing, hand fumbling, or grasping, leg pedalling or kicking, and whole-body rotation, cannot be reproducibly evoked during cortical stimulation, suggesting that these represent release phenomena with no specific cortical representation. In their extreme form, complex movements (the term 'complex' refers to the complexity of the movement, and not the state of consciousness) can present as 'bizarre' behaviour inappropriate for the situational context, such as jumping, rocking, thrashing, shouting, whistling, or kissing).

Alteration of awareness is a common and disabling feature of generalized and focal epilepsies arising from virtually any brain area. Alteration of awareness is thus not a symptom with localizing or lateralizing value. The commonly used term 'absence' refers to a brief (typically 5–10 seconds) generalized seizure defined by loss of consciousness with no or very subtle motor manifestations, and immediate postictal recovery, associated with generalized 3 Hz spike and wave complexes on EEG. Therefore, a focal seizure with loss of awareness is not an absence seizure.

Autonomic symptoms and signs are common in focal and generalized convulsive seizures, and usually reflect sympathetic activation (e.g. tachycardia and hyperventilation), however, bradycardia and apnoea may also occur. Gastrointestinal manifestations include ictal nausea, vomiting, and defecation. Urogenital features of seizures are incontinence, ictal or postictal urinary urge, and genital sensations. Patients may also complain of a sensation of heat or exhibit flushing. Cerebral areas involved in the generation of autonomic features are the medial prefrontal cortex, insula, amygdala, and cingulate. Generally speaking, ictal autonomic manifestations have little lateralizing or localizing value. An exception is the typical rising epigastric sensation seen in mesial temporal lobe epilepsy.

A further layer of localizing symptoms and signs in epileptic seizures stems from the correlation of ictal and postictal features with information about the seizure 'focus' using MRI, ictal EEG, and, ultimately, cessation of seizures following resective neurosurgery. Localizing and lateralizing value of common ictal symptoms and signs are summarized in Tables 81.1 and 81.2.

Epilepsy syndromes

Epilepsy syndromes combine certain clinical features, such as seizure types, the age (group) of the patient, comorbidities, and sometimes

Table 81.1 Localizing and lateralizing value of epileptic auras

Aura subtype	Symptomatogenic zone	Lateralization	Commonly associated focal epilepsy syndrome
Somatosensory (tingling, crawling sensation)	Primary somatosensory cortex	Contralateral	Parietal lobe epilepsy
	Secondary somatosensory area	Ipsilateral (if unilateral)	Parietal and temporal lobe epilepsy
	Supplementary sensorimotor area (SSMA)	Contralateral (mostly)	Frontal and parietal lobe epilepsy
Elementary visual (flashes, stars, and so on)	Primary visual cortex	Contralateral	Occipital lobe epilepsy
Complex visual (formed visual hallucinations)	Temporooccipital junction, basal temporal lobe, limbic system	Contralateral (if unilateral)	Occipital and temporal lobe epilepsy
Elementary auditory (simple sounds or deafness)	Primary auditory cortex	Contralateral (if unilateral)	Temporal lobe epilepsy
Complex auditory (noises, voices, music)	Auditory association cortex and limbic system	Contralateral (if unilateral)	Temporal lobe epilepsy
Vertiginous	Temporo-occipital junction	Not lateralizing	Temporal lobe epilepsy
Olfactory	Orbitofrontal cortex, amygdala, insula	Not lateralizing	Mesial temporal and Frontal lobe epilepsy
Gustatory	Parietal operculum and basal temporal cortex	Not lateralizing	Temporal lobe epilepsy
Abdominal	Anterior insula, frontal operculum, SSMA	Not lateralizing	Mesial temporal lobe epilepsy
Fear	Amygdala, hippocampus, mesial frontal lobe	Not lateralizing	Temporal lobe and frontal lobe epilepsy
Déjà vu, jamais vu, revocation of complex memories	Uncus, entorhinal cortex, temporal neocortex, limbic system	Not lateralizing	Temporal lobe epilepsy
Whole-body sensations	Amygdala, entorhinal cortex, secondary somatosensory area, supplementary sensorimotor area	Not lateralizing	Temporal and frontal lobe epilepsy
Autonomic (palpitations, shortness of breath, feeling hot or cold, genitourinary urge)	Amygdala, insula, anterior cingulum, medial prefrontal cortex	Not lateralizing (often non-dominant)	Temporal and frontal lobe epilepsy

Adapted from *Epilepsy & Behavior*, Volume 20, issue 2, Nancy Foldvary-Schaefer, Kanjana Unnwongse, Localizing and lateralizing features of auras and seizures, pp. 160–6, Copyright (2011), with permission from Elsevier.

Table 81.2 Localizing and lateraling value of objective seizure manifestations

Ictal sign	Common symptomatogenic area or mechanism	Lateralization	Commonly associated focal epilepsy syndrome
Myoclonus, negative myoclonus	Primary motor cortex, premotor cortex	Contralateral (if unilateral)	Frontal lobe epilepsy
Clonic jerks	Primary motor cortex, premotor cortex, SSMA	Contralateral (if unilateral)	Frontal lobe epilepsy
Tonic contractions or tonic posturing	Primary motor cortex, SSMA; activation of basal ganglia	Contralateral (if unilateral)	Frontal and temporal lobe epilepsy
Asymmetric limb posturing	SSMA, precentral area	Not lateralizing	Frontal and temporal lobe epilepsy
Immobile limb	Activation of negative motor areas or ictal exhaustion of primary or premotor cortex	Contralateral	Frontal lobe epilepsy
Automatisms	Orbitofrontal area, cingulum, opercular/insula cortex, mesial frontal area anterior to SSMA	Not lateralizing	Temporal, frontal, and parietal epilepsy
Automatisms with preserved awareness	Orbitofrontal area, cingulum, opercular/insula cortex, mesial frontal area anterior to SSMA	Non-dominant	Temporal, frontal, and parietal epilepsy
Eye and head version (sustained deviation to one side, often associated with hyperextension of the neck)	Frontal eye field, extrastriate cortex, premotor areas	Contralateral	Frontal epilepsy, also seen prior to secondary generalization of seizures arising in temporal, parietal, or occipital lobe
Ictal/postictal aphasia[1]	Anterior and posterior language areas, arcuate fasciculus	Dominant	Temporal and frontal lobe epilepsy
Ictal speech[2]	Excitation of non-dominant hemisphere or Inhibition of dominant hemisphere	Non-dominant	Temporal and frontal lobe epilepsy
Laughter	Hypothalamus, antero-mesial frontal area, basal temporal area	Not lateralizing	Temporal and frontal lobe epilepsy

SSMA, supplementary sensorimotor area.

[1] Ictal/postictal aphasia is defined as language impairment out of proportion to impairment of awareness

[2] Ictal speech is defined as intelligible speech during impaired of awareness

genetic information. While knowledge in the latter domain is rapidly expanding, this information is typically of little relevance to the neurosurgeon. Focal epilepsy syndromes are traditionally divided by anatomical localization of the epileptogenic zone (i.e. the area that is necessary and sufficient to generate seizures). It is important to note that none of the listed 'typical' seizure manifestations are absolutely specific for the given anatomical location. One reason for this is that the area of seizure origin (ictal onset zone) may be distinct from the area that generates the first seizure symptoms (symptomatogenic zone). For example, a rising epigastric sensation ('abdominal aura') is a classic symptom of mesial temporal lobe epilepsy, although this symptom can be evoked by electrocortical stimulation of the anterior insula, and can therefore occur in insular epilepsy as well.

Mesial temporal lobe epilepsy (mTLE) is the most common focal epilepsy syndrome. Common pathological substrates of mTLE are hippocampal sclerosis, cavernoma, low grade brain tumours, focal cortical dysplasia, encephalomalacia, and hamartomas. However, about 30–40% of patients have no identifiable pathology on MR imaging (Tatum, 2012). Patients with mTLE often report a history of febrile convulsions, CNS infection, or precipitating CNS injury in early childhood. There is often a latency period of 5–20 or more years prior to the onset of habitual seizures. Typical aura symptoms are a rising epigastric sensation, nausea, or unnatural and usually unpleasant olfactory or gustatory hallucinations, as well as sensations of familiarity (déjà vu, déjà entendu), or estrangement from the environment (jamais vu, jamais entendu), complex visual or auditory hallucinations, affective symptoms, or fear. These symptoms have no lateralizing value (Ferrari-Marinho et al., 2012).

In neocortical temporal lobe epilepsy (nTLE), the seizure onset tends to occur in early adulthood. Typical aura symptoms, reported by about 50–75% of patients, are simple auditory hallucinations (ringing or buzzing noises), muffled or distorted auditory perception (e.g. echoes), and a sensation of dizziness, unsteadiness, or vertigo.

Common objective symptoms of seizures arising in the temporal lobe are loss of awareness, semi-purposeful oral and manual automatisms, and dystonic posturing of contralateral limbs (Kuba et al., 2010). Some patients exhibit more complex behaviours such as wandering, drinking, or kissing, the latter two associated with non-dominant onset (Rashid et al., 2010). Autonomic features such as mydriasis, hypersalivation, vomiting, piloerection, and heart rate alterations are often seen. In TLE, symptoms tend to evolve gradually over the course of tens of seconds. The postictal period is characterized by confusion and amnesia for the seizure. Variable language impairment, ranging from global aphasia to word finding difficulties, is a common postictal symptom in seizures arising from the dominant temporal lobe.

Typical seizure features of frontal lobe epilepsy (FLE) reflect the complex functional connections within the frontal lobe and to neighbouring temporal, insular, and parietal areas. Auras in FLE are often non-specific. Patients may report or exhibit a facial expression of anxiety or fear, epigastric auras, and déjà vu (von Lehe et al., 2012), or report an ill-defined sensation of movement in the head ('cephalic aura'; see Canuet et al., 2008), sometimes associated with blurred vision (Beauvais et al., 2005). Objective behavioural manifestations of seizures involving the prefrontal areas often appear unnatural or bizarre, such as bicycling or scissoring leg automatisms, shuddering, pelvic thrusting, jumping, kicking, thrashing, crawling, and unformed vocalizations (Wehner et al., 2017). Seizures involving the supplementary sensorimotor area (SSMA) feature symmetrical or asymmetrical tonic contractions of face, throat, and limb muscles (Unnwongse et al., 2012), whereas involvement of the primary motor cortex is suggested by unilateral clonic jerking, often in a 'Jacksonian march' (i.e. sequentially involving the face, upper and lower extremity, or vice versa). Loss of postural tone (ictal atonia) may lead to head drop or falls. Awareness is often preserved in focal seizures involving the elementary motor system, even when bilateral motor features are present.

Seizure onset and offset in FLE are often abrupt, the seizures often occur repeatedly during sleep, and are typically shorter (on the order of 30 ± 15 seconds) than those seen in TLE.

The characteristic aura of seizures arising in the parietal lobe is a sensation of numbness, tingling or crawling in contralateral hemibody areas, in particular if presenting as a Jacksonian march. Other subjective symptoms are a disturbance of body image, illusions of movement, vertigo, and complex visual or auditory illusions. Objective behavioural manifestations are non-specific and may reflect ictal propagation into primary motor areas or SSMA (focal clonic activity contralateral to the side of seizure onset, tonic posturing), or the temporo-limbic system (behavioural arrest, automatisms, Wehner et al., 2017). Parietal lobe epilepsy therefore appears to be characterized by the absence of specific features (except for the somatosensory aura), and has been named the 'great imitator' among focal epilepsy syndromes (Ristic et al., 2012).

Patients with occipital lobe epilepsy (OLE) often report visual auras, ranging from flickering or flashing lights or shapes to distortions of proportions and colours, or formed visual hallucinations. Epileptic visual auras are shorter (seconds to few minutes) than visual auras reported by migraineurs (4–20 minutes, Adcock and Panayiotopoulos, 2012). Paraesthesias, epigastric sensations, and experiential symptoms suggest involvement of adjacent parietal or temporal-limbic areas (Bien et al., 2000; Jobst et al., 2010). Objective ictal manifestations in OLE are rapid eye blinking or eyelid flutter (Kun Lee et al., 2005; Tandon et al., 2009), and pursuit-like involuntary eye movements or nystagmus (Adcock and Panayiotopoulos, 2012). Depending on the seizure propagation, further signs mimic those seen in TLE (e. g. loss of contact, oral and gestural automatisms) and FLE (e.g. dystonic posturing and hyperkinetic automatisms; see Jobst et al., 2010).

Importantly, motor manifestations of epileptic seizures vary with age. Whereas myoclonic or bilateral tonic features and infantile spasms are the predominant semiology in infants and young children (Nordli, 2013), motor features and lateralizing signs tend to become more prevalent and prominent in parallel to developmental brain maturation (Fogarasi et al., 2007). In older people, secondarily generalized seizures and prolonged postictal symptoms such as confusion, memory impairment, and Todd's paresis are more common compared to younger patients (Stefan et al., 2014).

Status epilepticus

Most seizures terminate spontaneously after a few minutes. The term status epilepticus refers to the most extreme form of a seizure that does not self-terminate. The ILAE has recently revised its definition of status epilepticus as 'a condition resulting either from the failure

of the mechanisms responsible for seizure termination or from the initiation of mechanisms which lead to abnormally prolonged seizures (after time point t1). It is a condition that can have long-term consequences (after time point t2), including neuronal death, neuronal injury, and alteration of neuronal networks, depending on the type and duration of seizures' (Trinka et al., 2015). More than half of the patients with status epilepticus have an acute or remote central nervous system lesion or a systemic medical illness at the time of presentation. From a clinical perspective, generalized tonic-clonic seizures should be terminated within five minutes, and focal seizures with impaired consciousness within ten minutes. Treatment should be rapidly escalated if needed to minimize the long-term consequences.

While the clinical presentation of status epilepticus follows the same principles discussed earlier for epileptic seizures, the ictal symptoms and signs may change over a short period of time due to the highly dynamic nature of status epilepticus. Importantly, prominent motor symptoms in generalized convulsive status epilepticus tend to devolve over time, likely due to exhaustion of the underlying neuronal networks responsible for the generation of these symptoms. However, the pathological ictal activity in the brain may continue (non-convulsive status epilepticus). Therefore, non-convulsive status epilepticus needs to be considered and evaluated by EEG recordings in patients with unexplained coma or alteration of awareness, or patients who do not regain consciousness as expected following an acute brain injury.

Epilepsia partialis continua (EPC) refers to persistent regular or irregular clonic muscle twitching that affects a limited part of the body, typically distal rather than proximal body parts. The primary motor cortex is indispensably involved, and hemiparesis or other cortical based deficits are commonly associated (Bien and Elger, 2008). EPC usually has a symptomatic aetiology (most commonly vascular or inflammatory disorders, tumours, and metabolic-toxic disorders).

Structural causes of epilepsy

In neurosurgical practice, identifying a structural cause of epilepsy is important as resection of the abnormality may provide the best opportunity for seizure freedom (**Box 81.2**). Focal cortical dysplasias (FCDs) represent the commonest malformation of cortical development (MCD) encountered in epilepsy surgery. The development of a functional laminated human cerebral cortex is a multistaged process, which includes cell proliferation, differentiation, migration, synaptogenesis, and cellular reorganization. Disruption at any point during cortical lamination, neuronal migration, differentiation, and growth may result in MCD and may affect one discrete region, multiple lobes, or an entire hemisphere. In 2011, the ILAE reported a classification system incorporating histology, clinical presentation, and radiology (Blümcke et al., 2011; **Table 81.3**).

FCD types I and III result from cortical defects or injury at postmigrational stages. FCD I may be a result of severe prematurity, hypoxic ischaemic injury, head trauma, intracranial bleeding, or stroke during pre-/perinatal stages. It is considered an isolated malformation with abnormal cortical columnar disorganization in a radial (Ia; **Fig. 81.1**), tangential (Ib) or mixed (Ic) pattern. FCD III is associated with additional primary pathology that occurred early in development including hippocampal sclerosis (IIIa), tumours causing epilepsy, for example, dysembryoplastic neuroepithelial tumours (DNT: IIIb), adjacent vascular malformations (e.g. AVM, cavernoma, and other epileptogenic lesions including head injury, encephalitis, and hypoxic ischaemic injury). These lesions are typically seen on MRI, however, a causal event may not be identified.

FCD II is a result of abnormal cell development and maturation and is characterized by dyslamination and dysmorphic neurons (**Fig. 81.2**). Patients with FCD II typically exhibit medically refractory epilepsy at an earlier age, with a higher degree of cognitive decline. Balloon cells are the defining cell type of FCD IIb and may express neuronal nuclei (NeuN), glial fibrillary acid protein (GFAP), microtubule-associated protein 1B, vimentin, and nestin, suggesting that these cells are of mixed origin and retain features of immaturity. The balloon cells may also express stem cell markers including Sox2, c-Myc, and Klf4, which have been linked to enhanced mammalian target of rapamycin (mTOR) signalling pathway. Targeting the mTOR pathway with inhibitors may represent a promising novel treatment (Guerrini et al., 2015).

Box 81.2 Structural causes of epilepsy

- Focal cortical dysplasia
- Malformations of cortical development
- Hippocampal sclerosis
- Neurocutaneous syndromes
- Vascular malformations
- Hypothalamic hamartoma
- Brain tumours
- Acquired lesions
  - Abscesses
  - Inflammatory and infectious conditions
  - Ischaemic and haemorrhagic stroke

Table 81.3 Classification of focal cortical dysplasia

Focal cortical dysplasia secondary to cortical defects or injury at postmigrational stage of development	Type I Isolated dyslamination	Ia. Abnormal radial lamination Ib. Abnormal tangential lamination Ic. Abnormal radial and tangential lamination
	Type III Associated pathology	IIIa. Hippocampal sclerosis IIIb. Tumours associated with epilepsy (e.g. ganglioglioma, dysembryoplastic neuroepithelial tumour) IIIc. Vascular malformations (e.g. cavernoma) IIId. Other principal lesions during early life (e.g. head trauma, hypoxic ischaemic injury, encephalitis)
Cortical dysgenesis due to abnormal cell development and maturation	Type II Isolated dyslamination with dysmorphic neurons	IIa. Large dysmorphic neurons IIb. Large dysmorphic neurons and balloons cells

Reproduced with permission from Ingmar Blümcke, Maria Thom, Eleonora Aronica, et al., The clinicopathologic spectrum of focal cortical dysplasias: A consensus classification proposed by an ad hoc Task Force of the ILAE Diagnostic Methods Commission, *Epilepsia*, Volume 52, Issue 1, pp. 158–74, Copyright © 2010 John Wiley and Sons.

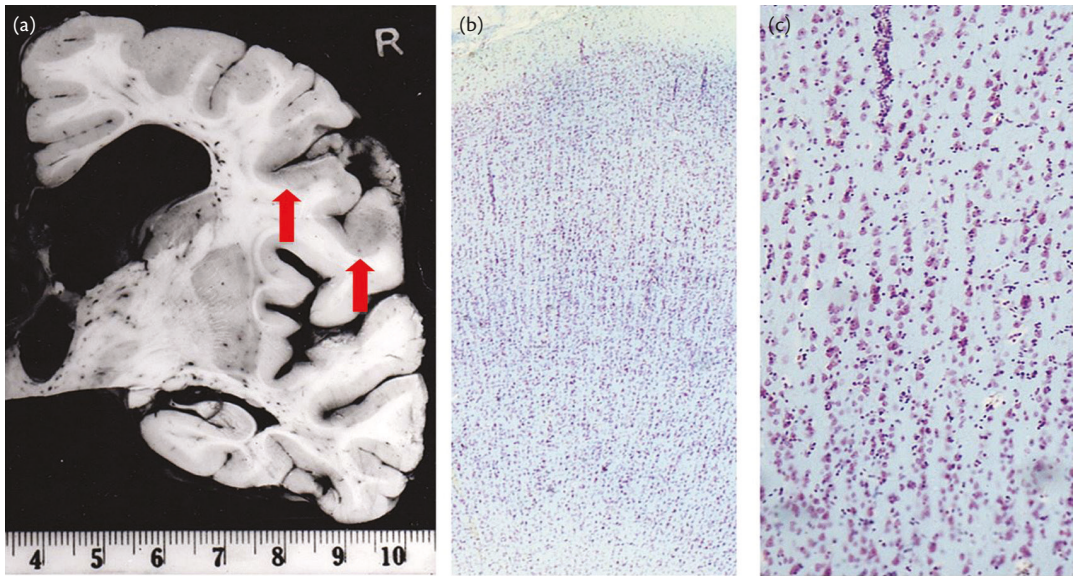

Fig. 81.1 Pathological and histological features of FCD 1a. (A) Post-mortem specimen of a 22-year-old female who died of sudden unexplained death in epilepsy (SUDEP) with history of epilepsy (generalized and partial seizures) since the age of 1 year, hemispherectomy aged 5 years in 1970s (surgical tissue not available for review). Examination of right hemisphere sections showed several regions of focal cortical dysplasia involving frontal and temporal lobe with patchy distribution. (B, C) Type FCD Ia in the ILAE 2011 classification: Nissl stain of the abnormal region highlights the preservation of the columnar architecture of the cortex with characteristic small sized neurones arranged in radial patterns (B: 10×; C: 20×)

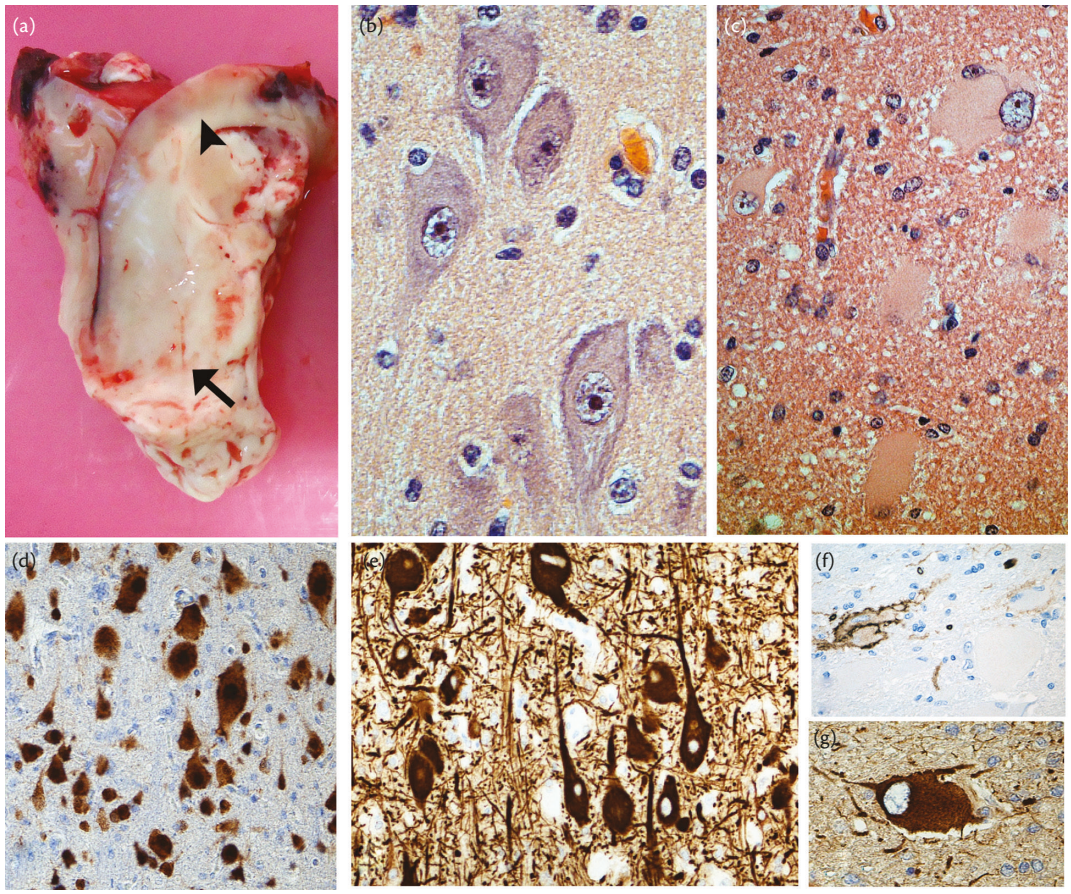

Fig. 81.2 Pathological and histological features of FCD IIb. (A) Macroscopic appearances of FCD IIb with poor demarcation between the grey and white matter (arrow) compared to adjacent well-defined cortex (arrowhead). (B) Haematoxylin and eosin staining demonstrates dysmorphic neurones populating the FCD cortex (50×), and (C) balloon cells in the white matter (20×). (D) Abnormal neurones are larger than normal neurones as shown on NeuN and with excessive labelling for neurofilament as shown in (E). (F) Balloon cells show variable labelling for CD34 and also nestin in (G).

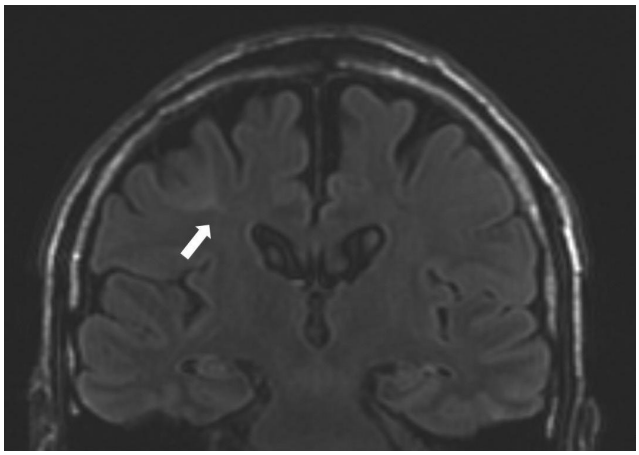

Fig. 81.3 Focal cortical dysplasia MRI characteristics. MRI FLAIR sequence demonstrating focal cortical thickening, abnormal gyral and sulcal patterns and the transmantle sign (arrow) which are most commonly seen in FCD IIb. The transmantle sign is a subcortical white matter hyperintensity extending to the ventricle.

A typical epilepsy protocol MRI at 1.5 or 3 Tesla includes T1- and T2-weighted volumetric imaging, and fluid-attenuated inversion recovery (FLAIR) images (Duncan et al., 2016). Features of FCD include cortical thickening, abnormal gyral and sulcal patterns, and the transmantle sign most commonly seen in FCD IIb (Fig. 81.3). The transmantle sign is a subcortical white matter hyperintensity extending to the ventricle, best seen on FLAIR sequence and affords better seizure control postsurgical resection than patients with FCD I (Wang et al., 2013). It is unknown whether this is related to intrinsic lower epileptogenicity or easier anatomical recognition of the epileptogenic tissue. Electrophysiological studies on balloon cells demonstrated that they are electrically 'silent', and it has been hypothesized that their presence could promote synaptic reorganization in the surrounding cortex that may result in a net increase in excitability in the tissue (Cepeda et al., 2003). An ongoing controversy is whether seizures arise within the dysplastic cortex, from the surrounding brain, or both. This is an important issue, as a significant proportion of patients remain medically refractory after surgical resection of the lesion defined by imaging only.

Within epilepsy surgical programmes for the management of medically refractory epilepsy, hippocampal sclerosis (HS) is one of the commonest pathologies ranging from 33–66% (for a review, see Thom, 2014). The 2013 ILAE classification of HS (Blümcke et al., 2013) is based on patterns of neuronal loss and gliosis as objective measures of sclerosis within the different hippocampal subfields (Fig. 81.4). In HS type 1 (previously termed classical sclerosis), neuronal loss and gliosis is found to a greater extent in subfield CA1 but also in CA4 and CA3, with sparing of CA2. This represents 60–80% of HS cases and has a common association with febrile seizures. It has the highest rates of seizure freedom postoperatively, with 70–85% seizure freedom at 2 years and 50% at 10 years. In HS type 2, the neuronal loss and gliosis is predominantly seen in CA1 subfield (5–10% of HS cases). In HS type 3, it is only present in the CA4 subfield with end folium sclerosis (3–7% of HS cases), and is associated with a dual pathology such as DNT or cavernoma. HS types 2 and 3, typically have an older age at epilepsy onset and have poorer postsurgical seizure-free outcomes in some series. Currently it is unknown why there is regional selectivity of pyramidal cell loss in different hippocampal subfields. It is likely, however, that different modulatory networks, altered excitatory pathways and inhibitory inputs, and efficacy of endogenous neuroprotective mechanisms are involved.

The aetiology of HS is still debated, however is likely to be multifactorial. Status epilepticus, repetitive generalized or partial seizures, and prolonged febrile seizures do not inevitably lead to HS. Although HS is considered a sporadic condition, there are likely to be other susceptibility factors involved. Inflammation with activation of the innate and adaptive immune system has been reported in HS, mechanisms for seizure-induced neuronal loss and an underlying abnormality in the developmental template may contribute (Thom, 2014). Imaging features of HS include hippocampal atrophy, volume loss on T1 and increased signal intensity on T2-weighted images and FLAIR (Fig. 81.5). Automated segmentation can quantify hippocampal sclerosis and is strongly recommended.

Anatomy of the limbic system

The circuit of Papez commences at the hippocampus and continues via the fornix to the mammillary bodies. Fibres are then relayed via the mammillothalamic tract to the anterior thalamic nucleus and via projections to the cingulate gyrus and back to the hippocampus. The limbic system comprises of the circuit of Papez and its associated subcortical nuclei including the amygdala, hypothalamic, and septal nuclei. It is composed of white and grey matter and phylogenetically is one of the most primitive parts of the brain involved in emotion, memory, and learning. The limbic system is one of the networks that can propagate seizure spread particularly from mesial temporal pathologies. For an anatomical review see Shah et al. (2012), and for a recently revised limbic system model incorporating tractography, see Catani et al. (2013) (also see Fig. 81.6).

The hippocampus forms the medial part of the floor of the temporal horn and rests on the subiculum, which forms the superior surface of the parahippocampal gyrus. The hippocampus is separated from the subiculum and parahippocampal gyrus by the hippocampal fissure. The white matter alveus borders the lateral ventricle and continues posteriorly as the fimbria, which gives rise to the crus of the fornix. The fornix is a projection tract connecting the hippocampus with the mamillary bodies, anterior thalamic nuclei, and hypothalamus. The crus of the fornix curves up and laterally over the pulvinar of the thalamus. It merges with the contralateral crus to form the body of the fornix beneath the splenium of the corpus callosum. The two crura of the fornices are connected by the hippocampal commissure. The body of the fornix runs forward to the anterior end of the thalamus, where the fibres of the two sides again separate and arch downwards in front of the intraventricular foramen of Monroe as the columns of the fornix. As the fibres of the fornix approach the anterior commissure, they divide. The majority forms the postcommissural portion, which terminate in the mammillary body, and a minority form the precommissural portion with connections to the septal nuclei, hypothalamus, and nucleus accumbens. Fibres then ascend to the anterior nucleus of the thalamus, forming the mammillothalamic tract. From the anterior nucleus of the thalamus, fibres merge with the fibres of the anterior limb of the internal capsule to reach the cingulate gyrus.

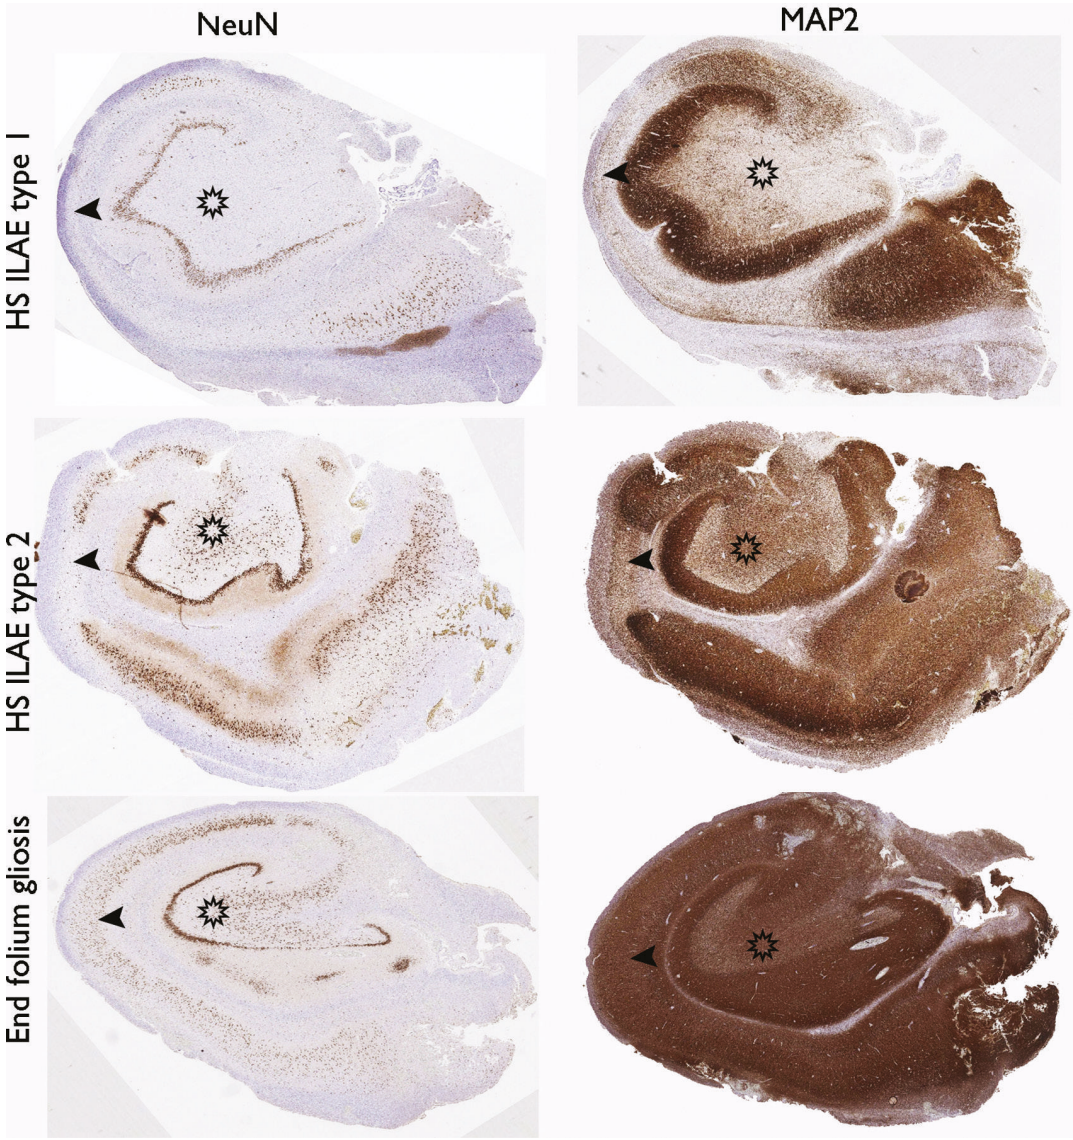

Fig. 81.4 Hippocampal sclerosis (HS) subtypes. The column on the left shows hippocampal sections stained with NeuN (neuronal nuclei) and on the right with MAP2 (neuronal cell bodies and dendrites). The asterisk shows the CA4 and the arrow the CA1. These are the main regions, which determine the patterns of HS in the 2013 ILAE classification of hippocampal sclerosis. In HS type 1, there is neuronal loss in CA4 and CA1. In type 2, the main neuronal loss is restricted to CA1. In the bottom row there is minimal loss from CA4. NB: In HS type 3, neuronal loss and gliosis is seen in CA4 only, while CA1 is preserved.

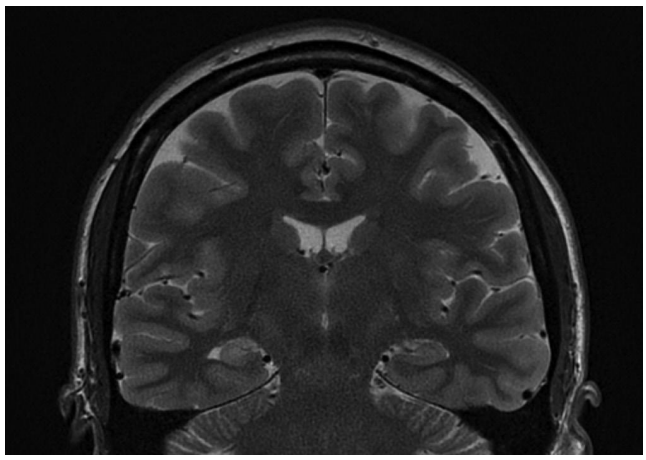

Fig. 81.5 Hippocampal sclerosis MRI characteristics. T2-weighted coronal MRI demonstrating right hippocampal sclerosis with increased signal intensity and hippocampal atrophy resulting in a more prominent ventricular temporal horn.

The cingulum is an association bundle that runs superior and parallel to the corpus callosum. Anteriorly, the fibres run below the rostrum of the corpus callosum in the subcallosal gyrus. Posteriorly, the cingulum narrows above the splenium, forming the isthmus of the cingulum. It continues below to end in the anterior parahippocampal gyrus adjacent to the hippocampus. The parahippocampal gyrus lies at the junction of the medial and inferior portions of the temporal lobe. The entorhinal area comprises the anterior aspect of the parahippocampal gyrus and contains the uncus, which contains the amygdala. However, the posterior aspect is poorly demarcated. It has many afferent and efferent connections with the hippocampus, cortical association areas, and forms an important relay centre. Laterally and anteriorly, the parahippocampal gyrus is limited by the rhinal sulcus (the anterior continuation of the collateral sulcus) and marks the lateral extent of the entorhinal area of the parahippocampal gyrus. Posteriorly, the parahippocampal gyrus is divided by the anterior calcarine sulcus into the isthmus

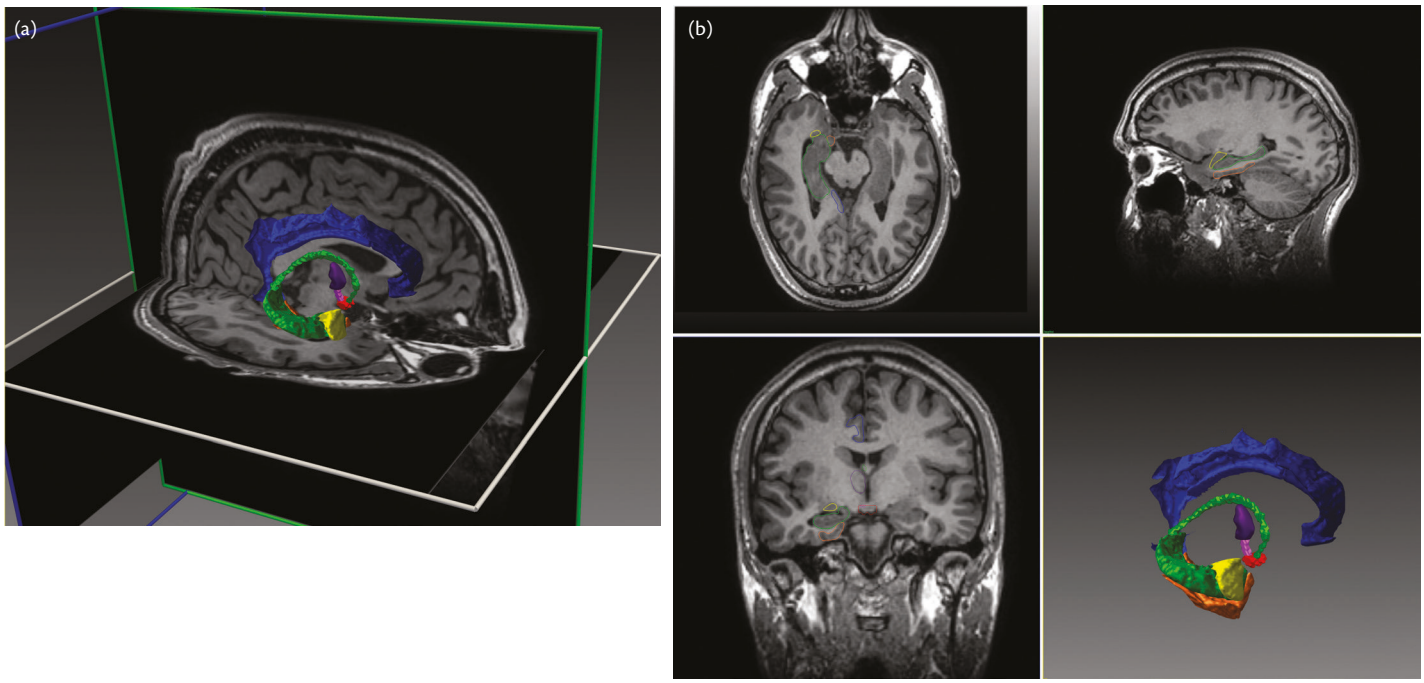

Fig. 81.6 Segmentation of the limbic pathway outlined on T1-weighted MRI: hippocampus-fornix = green, mammillary body = red, mammillothalamic tract = pink, anterior thalamus = purple, cingulum = blue, parahippocampal gyrus = orange, amygdala = yellow.

of the cingulate gyrus superiorly, which continues as the cingulate gyrus, and the parahippocampal gyrus inferiorly, which continues as the lingual gyrus. The amygdala is a complex of nuclei located entirely within the confines of the uncus. The amygdala complex gives rise to two major pathways, the stria terminalis and the ventral amygdalofugal pathway, and has widespread connections to the limbic system, thalamus, and hypothalamus.

Epilepsy—diagnosis and assessment

Richard Selway

Introduction

Epilepsy was described as early as the second millennium before Christ; it was referred to in Sumerian and later Babylonian texts as the *'falling sickness'*. It is derived from the Greek word *epilambanein* which means to seize or to attack. The term *seizure* itself is of Latin origin derived from *sacire*—to claim.

Thus for much of its history, epilepsy was viewed as a paroxysmal disorder with supernatural connotations—sufferers were deemed possessed by an evil spirit notwithstanding Hippocrates' reflection in his famous fifth-century treatise on *'the sacred disease'* that the brain was the seat of epileptic attacks.

With the development of neurology as a specialty in its own rights in the nineteenth century, our understanding of epilepsy evolved. John Hughlings Jackson was instrumental in relating focal seizures to local brain disorders, beginning a long-running debate concerning the distinction between primary idiopathic epilepsy (where the brain is macroscopically normal) and secondary symptomatic epilepsy (with a defined underlying pathology) and whether one or the other represents 'true epilepsy'.

Jackson and Todd introduced the concept of abnormal electrical discharges which gained further credence following the development of the electroencephalogram by Hans Berger in 1929.

Epilepsy was now being viewed as an electromagnetic disorder, yet it never truly lost its association with alienation. For much of the nineteenth century, disorders of mood, behaviour, or personality were often labelled as epileptic in nature.

More recently, there has been an acknowledgement of the socioeconomic burden of the condition, a recognition that it still carries a significant social stigma. Furthermore, as our understanding of neural networks has improved, novel techniques of neuromodulation have been developed as an adjunct to more traditional medical and resective therapeutic measures.

What is a seizure?

A transient occurrence of signs and/or symptoms caused by abnormal, excessive, or synchronous neuronal activity within the brain.

What is epilepsy?

A disorder of the brain characterized by an enduring predisposition to generate epileptic seizures. In clinical terms, this generally implies two unprovoked seizures at least 24 hours apart.

A more practical definition was produced by the ILAE (International League Against Epilepsy) task force in 2014 *(Fisher et al., ILAE Official Report, Epilepsia 55(4): 475–82, 2014)*:

Epilepsy is a disease of the brain defined by any of the following:

1. At least two unprovoked (or reflex) seizures occurring more than 24 hours apart
2. One unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years
3. Diagnosis of an epilepsy syndrome

Unprovoked refers to the absence of underlying acute conditions that can induce seizures in subjects who would not otherwise suffer attacks, for example, alcohol withdrawal, electroconvulsive therapy, encephalitis, head injury, or hypoglycaemia.

In a small proportion of patients, seizures can be triggered by specific stimuli that do not induce attacks in the general population (flashing lights, visual patterns, music, reading, intellectual activity). They are called *reflex seizures*. See Chapter 82 for a full discussion of seizure classification and definition.

Epidemiology

Epilepsy is the commonest serious neurological condition. It affects over 60 million people worldwide irrespective of gender or race, with an annual incidence of 45–50 cases per 100 000 people per year in developed countries. The point prevalence of epilepsy is 1% in both developed and developing countries with a lifetime incidence of 4–5%.

Incidence varies greatly with age (see Fig. 82.1).

There are two peaks in developed countries: young age, particularly during the first few months of life (half of all cases start in

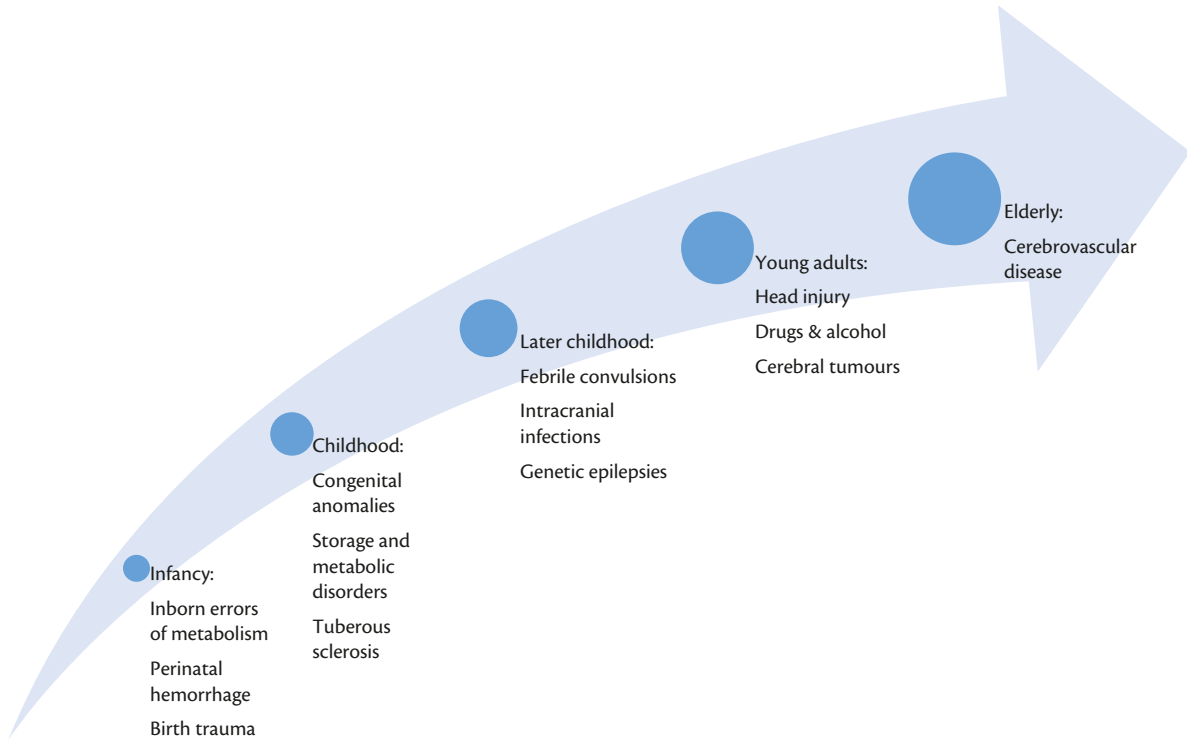

Fig. 82.1 Aetiology by age. Incidence, prevalence, cumulative incidence, and mortality for epilepsy in Rochester, Minnesota, 1935–1984.
Reprinted from Mayo Clinic Proceedings, Volume 71, issue 6, W. Allen Hauser, John F. Annegers, Walter A. Rocca, *Descriptive Epidemiology of Epilepsy: Contributions of Population-Based Studies From Rochester, Minnesota*, pp. 576–86, Copyright (1996), with permission from Elsevier.

childhood or adolescence) and in people over 65 years (due to cerebrovascular disease).

Overall, the incidence in children appears to be declining while there has been a sharp rise in older people. Indeed, old age has become the most common time of life to develop epilepsy. In developing countries, there is a third peak in young adults, which may be partially related to cerebral trauma.

Epilepsy is also the second commonest cause of mental health disability particularly in young adults. One in three patients report significant concerns about their mood. Depression, anxiety, and psychosis are common and have a significant impact on the patients' quality of life. Depression in under-recognized and often undertreated; the overall suicide rate in depressed patients with epilepsy is five times higher than that in the general population. Anxiety markedly compromises psychosocial functioning while psychosis has been reported in as many as 15% of patients with temporal lobe epilepsy.

Very few aspects of daily living remain unaffected by a diagnosis of epilepsy. It impacts on social interactions, employment, and driving, and often necessitates significant lifestyle modifications if not restrictions. Thus, it carries a significant burden over and above the clinical manifestations of the disorder although it should be noted that the incidence of seizures is not directly proportional to a patient's quality of life (Gillam, 1982).

Despite this, most patients with epilepsy do actually have a good prognosis although this is strongly dependent on the underlying cause. Many childhood epilepsy syndromes burn themselves out by the late teens or early adult years. Conversely, a significant minority suffer a relapsing-remitting course or lifelong disabling seizures. Markers of poor prognosis include a symptomatic cause, generalized epileptiform activity on an electroencephalogram (EEG), poor response to initial antiepileptic drug (AED) treatment, a concurrent psychiatric history, and a family history of epilepsy.

It is estimated that two-thirds of people with epilepsy become seizure-free on anticonvulsant drugs. The remainder suffer persistent seizures and are of particular interest to the neurosurgeon as a proportion (up to 60% depending on selection criteria) may benefit from interventions that significantly alleviate their seizure burden or even effect a cure in select cases (Brodie et al., 2012).

Sudden unexplained death in epilepsy (SUDEP)

The standardized mortality ratio (SMR = the number of observed deaths per number of expected deaths) compares mortality in a group with a specific illness to age and sex-matched controls. In patients with epilepsy, it is two to three times above that of the general population.

When deaths related to the underlying aetiology, accidents and injuries, and associated psychiatric complications are excluded, it still appears that epileptics are at risk of dying abruptly of no clear cause. SUDEP may account for up to 17% of all epilepsy-related deaths (incidence 0.35–10 per 1000 patients per year).

SUDEP is defined as 'sudden, unexpected, witnessed or unwitnessed, non-traumatic, and non-drowning death in patients with epilepsy, with or without evidence of a seizure, and excluding documented status epilepticus, in which post-mortem examination does

not reveal a toxicological or anatomical cause of death'. While some of these may be related to undetected seizures, some may also be related to cardiac dysrhythmias which can be an associated feature.

Genetic syndromes

Genetic susceptibility may be syndromic or non-syndromic with a range of aetiologies including morphological, metabolic, and vascular anomalies. Genetic screening of children with seizures should be considered where there are associated features or a family history.

Febrile convulsions

Febrile seizures are common with 5% of the general population having had one. They develop in association with fever (usually during the rapidly rising phase) with no evidence of any other cause. By definition they occur between 5 months and 5 years of age and are generally considered benign if uncomplicated although 1 in 3 children will have recurrent episodes and 5% later develop epilepsy (up to 50% of patients with mesial temporal sclerosis have a history of febrile convulsions). Such seizures occurring outside the specified age bracket should not be regarded in the same way, and carry a much worse prognosis.

The risk of developing epilepsy increases up to threefold when febrile convulsions have adverse features including a focal seizure, a seizure that last longer than 15 minutes, recurrence within 24 hours, focal neurological abnormalities, or a family history of epilepsy.

Treatment is usually symptomatic and supportive with administration of an antipyretic such as paracetamol. Tepid sponging and long-term AED treatment are not recommended in uncomplicated cases.

Diagnosis

Broadly speaking, seizures can be classified as partial (focal) or generalized. The former originate from cortical structures and, while they may become secondarily generalized, their semiology may allow seizure onset to be lateralized to a specific hemisphere or localized to a specific lobe of the brain or even a specific area within that lobe (e.g. lateral temporal neocortex vs. mesial temporal structures). By contrast, generalized seizures may be thought to originate from the deeper midline structures with simultaneous spread to both cerebral hemispheres. ('The centrencephalic theory').

In the traditional nomenclature of seizures, if awareness is maintained they are called 'simple' attacks, but with loss of awareness they are 'complex' seizures.

A seizure may be characterized by a *prodrome*, an *aura*, an *ictus*, and a *postictal period*—all of which may help to localize the seizure onset within the central nervous system.

The prodrome refers to changes in behaviour or mood which may precede an attack, sometimes by several hours. It is not regarded as part of the electrical seizure itself.

The aura describes symptoms experienced by the subject that immediately precede an attack, such as a feeling in the stomach in temporal lobe seizures. Electrically the aura is part of the seizure (a simple partial seizure, which may then spread to a wider part of the brain to produce the objective attack or ictus). Following a seizure, the patient may be disoriented or demonstrate automatisms, the so-called postictal period.

Seizure semiology

The description of an attack (the 'semiology') is the first step in localizing seizure onset and spread. While the descriptions that follow are typical seizure propagation often results in a more complex picture. For example, probably most occipital partial seizures will spread into the mesial temporal structures producing a semiology with features of both areas. A very careful history and observation of typical seizures on video may allow the site of origin and the path of propagation to be understood (Table 82.1).

Temporal lobe epilepsy

Temporal lobe epilepsies are a heterogeneous group of disorders that are anatomically broadly divided into those originating from the lateral neocortex or the medial (mesial) regions of the temporal lobe (amygdala and hippocampus).

Mesial temporal lobe epilepsy is twice as common and most often secondary to hippocampal sclerosis, hence the term *mesial temporal sclerosis*. Other causes include tumours (particularly dysembryoplastic neuroepithelial tumours or DNETs), cortical dysplasia, hamartomas, and vascular lesions such as cavernous angiomas.

Mesial temporal sclerosis

Mesial temporal sclerosis is the commonest pathology in drug-resistant temporal lobe epilepsy and one of the most distinct epileptic syndromes with defined hippocampal pathology on MRI, neuronal loss in CA1 and CA3 regions of the hippocampus, a characteristic clinical picture and, crucially, postresection surgical relief.

It probably accounts for 20% of patients with epilepsy and 65% of those undergoing a temporal lobectomy for seizure control.

Seizure onset is usually just before puberty, typically around 12 years of age although half of all patients give a history of childhood febrile convulsions. A seizure typically begins with a vegetative aura, often described as a rising sensation in the pit of the stomach although complex olfactory or gustatory sensations may also occur. This is followed by a complex partial seizure with impairment of consciousness heralded by an initial behavioural arrest and stare followed by oro-alimentary and gestural automatisms (chewing, lip smacking, fumbling, or picking at the clothes) lasting a couple of minutes which the patient does not recall. There is often contralateral dystonic posturing. Postictal confusion is common as are affective symptoms such as psychosis or anxiety. Secondary generalization is exceedingly rare.

Radiological appearances are characteristic with evidence of hippocampal atrophy on MRI and high signal on T2 or FLAIR sequences while an EEG shows anterior temporal interictal spikes. See Figure 82.2.

Table 82.1 Lateralising and localizing features of seizures

Lateralising features	
Dominant hemisphere	Ictal and postictal dysphasia
Non-dominant hemisphere	Ictal speech Preserved awareness during ictal automatisms
Ipsilateral hemisphere	Unilateral eye blinking Manual automatisms
Contralateral hemisphere	Unilateral ictal clonic (i.e. rhythmic jerks) or dystonic (sustained muscle contraction) activity Upper limb dystonia
Localizing features	
Frontal lobe	Usually brief (<2 minutes) with stereotyped features and preserved awareness Often nocturnal with clustering Prominent motor features ('hypermotor seizures') sometimes violent but coordinated may be mistaken for night terrors, sleepwalking, or rage
Primary sensorimotor cortex	Tonic, clonic, myoclonic, or atonic Jacksonian march Todd's paresis postictally
Orbitofrontal cortex	Repetitive gestural automatisms Dyscognitive features—altered awareness or responsiveness Olfactory hallucinations Autonomic signs
Frontopolar cortex	Dyscognitive features Autonomic signs Axial convulsive movements causing falls Initial ipsilateral head and eye version Forced thoughts
Dorsolateral frontal cortex	Often tonic movements Aversive with contralateral head and eye movement (frontal eye field) Forced thoughts and acts (e.g. compulsion to stare at an object) Dysphasia if dominant lobe
Cingulate cortex	Gestural automatisms at onset with loss of awareness Affective aura (e.g. fear, depression, joy, anger) Autonomic features (e.g. palpitations, urge to urinate or defecate) Gelastic automatisms (i.e. laughing)
Central (supplementary motor cortex, frontoparietal operculum, paracentral lobule)	Abrupt onset/offset of asymmetric tonic posturing lasting <60 seconds with minimal postictal confusion Extension of upper limb contralateral to hemisphere of seizure onset Flexion of ipsilateral upper limb (described as a 'sign of four' posture as the arms are held in the shape of a 4) Contralateral head and eye deviation Loud vocalization or speech arrest at onset
Opercular/Insular	Facial clonic movements Laryngeal symptoms Difficulty articulating Hypersalivation Gustatory hallucinations
Parietal lobe	Contralateral sensory aura, usually paraesthesia +/– numbness, prickling, crawling May spread in a Jacksonian march Pain, typically burning Hallucination of distortion of body shape Micro/macrosomatognosia (shrunken/swollen body part) Hyper/hyposchematica (elongated/shortened body part) Sexual sensation affecting genitalia if paracentral lobule Language impairment with difficulty reading, calculating, or writing if dominant
Occipital lobe	Visual auras in the field contralateral to the hemispheric onset Multicoloured shapes (e.g. circles or flashes) Visual loss (e.g. amaurosis, scotoma, black-out, or white-out) Visual hallucinations (these more formed visual experiences tend to involve more anterior structures into the temporal lobe) Pictures of people, animals, or scenes—static or moving Visual illusions Alteration of visuospatial perception if non-dominant parietal lobe Micro/macropsia Teleopsia (object appears small and far) Palinopsia (visual perseveration) Epileptic nystagmus Fast component away from ictal onset, slow component towards it Oculomotor features (e.g. eyelid flutter, forced eye closure)

Table 82.1 Continued

Localizing features	
Temporal lobe	Complex aura (e.g. déjà vu, often epigastric rising sensation, or auditory buzzing) Behavioural arrest—patient stops what they are doing and stares into space Loss of awareness, said to represent the spread of a temporal seizure to involve the contralateral side as well (complex partial seizure) Automatisms—oro-alimentary +/– gestural Autonomic features—pallor, palpitations Postictal confusion and headache
Mesial temporal lobe	A distinctive aura, either in isolation or followed by behavioural arrest with slowly progressive impairment of awareness and oro-alimentary and manual automatisms Rising epigastric sensation or abdominal discomfort Déjà-vu, jamais-vu Chewing, lip smacking, swallowing Autonomic features Ipsilateral pupillary dilatation Contralateral upper limb dystonia, plus head and eye version Longer duration than lateral temporal seizures
Lateral temporal neocortex	Initial aura with auditory, complex visual, illusionary, or vertiginous features Buzzing or ringing sound, if heard in only one ear, suggests onset in contralateral hemisphere Shorter aura, earlier onset of altered awareness and shorter ictus More likely to evolve to a bilateral convulsion

While most patients with hippocampal sclerosis have predominantly unilateral disease, most will also have bitemporal electrical spikes on EEG and at least 30% will have apparent bilateral ictal EEG changes on video telemetry. In 11% ictal EEG onset appears to be contralateral to the true site of onset. This may either reflect bilateral seizure foci or bilateral dysfunction from a single focus with rapid seizure spread to the contralateral side. When recording from conventional scalp EEG electrodes the electrical source is often a long way away and rapid spread to contralateral structures may then propagate to the surface first on either side. In such cases, it is often useful to establish language dominance and the memory reserve of the contralateral hemisphere before embarking on a temporal resection.

The disorder may initially respond well to AEDs but seizures tend to become drug resistant from early adulthood onwards. Surgical resection (en-bloc anterior temporal lobectomy or more selective amygdalohippocampectomy) has an excellent outcome with up to 80% of patients becoming seizure-free.

Investigations

What information does an epilepsy surgeon need? Once the notion of medical intractability is demonstrated, further investigations are aimed at localizing the seizure onset and identifying any potential underlying lesions.

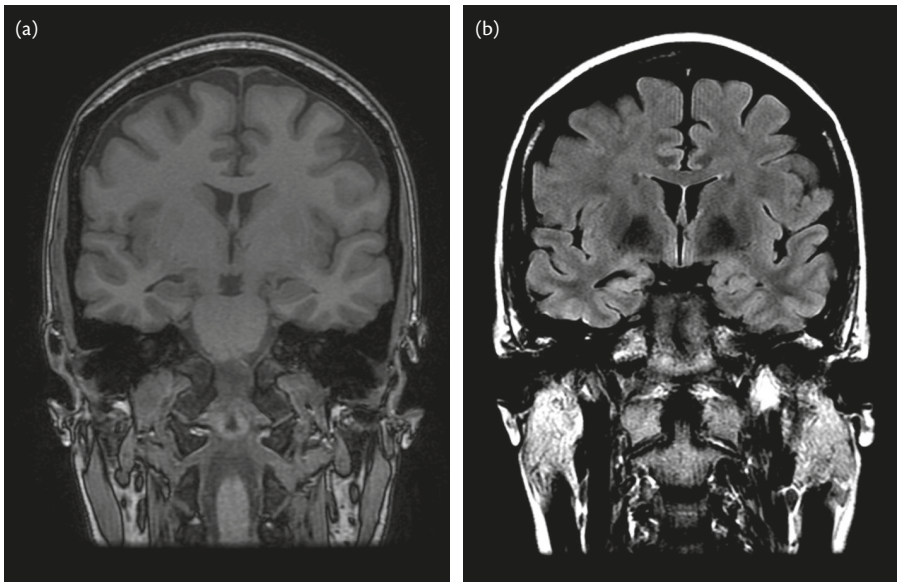

Fig. 82.2 Coronal view demonstrating volume loss, secondary dilatation of the temporal horn and signal change. Coronal SPGR (A) and FLAIR (B) MR sequences demonstrating low T2 signal and volume loss in right hippocampus.

This usually involves a combination of a high-quality MRI scan with FLAIR sequences to identify neoplastic, vascular or developmental pathologies, and scalp telemetry.

Electroencephalogram (EEG)

The EEG provides a record of electrical activity from different areas of the brain. It represents the compound electrical field generated by neuronal function (mainly from postsynaptic potentials in the cerebral cortex).

EEG recordings are usually obtained via scalp electrodes (*scalp telemetry*). *Video telemetry* allows electrical rhythms to be matched to concurrent clinical seizure activity to facilitate localization of an epileptogenic focus.

Surface electrodes are small silver discs that are placed on the patient's scalp to provide coverage of clinically relevant areas. The most commonly used convention for electrode placement is the '10–20' system where electrodes are placed and identified by letters and numbers, for example, F (frontal), T (temporal), Fp (frontopolar), with odd numbers covering the left hemisphere and lower values representing a more anterior and medial location (e.g. F7 would indicate left posterolateral frontal placement).

The EEG measures the potential difference (in millivolts) between paired electrodes. If adjacent electrode differences are displayed this is known as a bipolar montage. Alternative montages are useful to highlight particular EEG features or minimize artefact (i.e. interference) for example referential montage is used where a single specified contact is compared with all the others.

Ongoing electrical activity is called background activity. Several rhythms are identifiable varying with age, time, location, and clinical activity. Paroxysmal activity is sought as it may be epileptic in nature.

Figure 82.3 shows an EEG demonstrating a burst of alpha activity on eye closure.

Invasive EEG

Invasive EEG (iEEG), which requires surgical placement of recording electrodes intracranially, is utilized in selected cases as a stage in the work up prior to epilepsy surgery or for intraoperative monitoring during these procedures. EEG recordings from depth electrodes inserted into the brain parenchyma or within a lesion are called stereoencephalography (SEEG). EEG recordings from subdural grids or strip electrodes placed on the exposed brain surface are called electrocorticography (ECoG) which can be intra- or extraoperative. Following placement, extraoperative recording is performed off anticonvulsants for a period of typically 3–14 days, depending upon the seizure frequency, to establish the location of the epileptogenic zone.

Invasive EEG is employed whenever information from surface EEG is insufficient to allow precise targeting of the location of the seizure onset and the definition of the boundary of the epileptogenic zone. iEEG tests are valuable when there is discordance in the non-invasive investigations, or between the interictal data and the nature of the ictal episodes, in the presence of dual pathology or when the localization of the seizure onset is unclear for example, when bilateral ictal discharges are seen on EEG. Two further examples of this are the presence of bilateral independent temporal spikes on surface

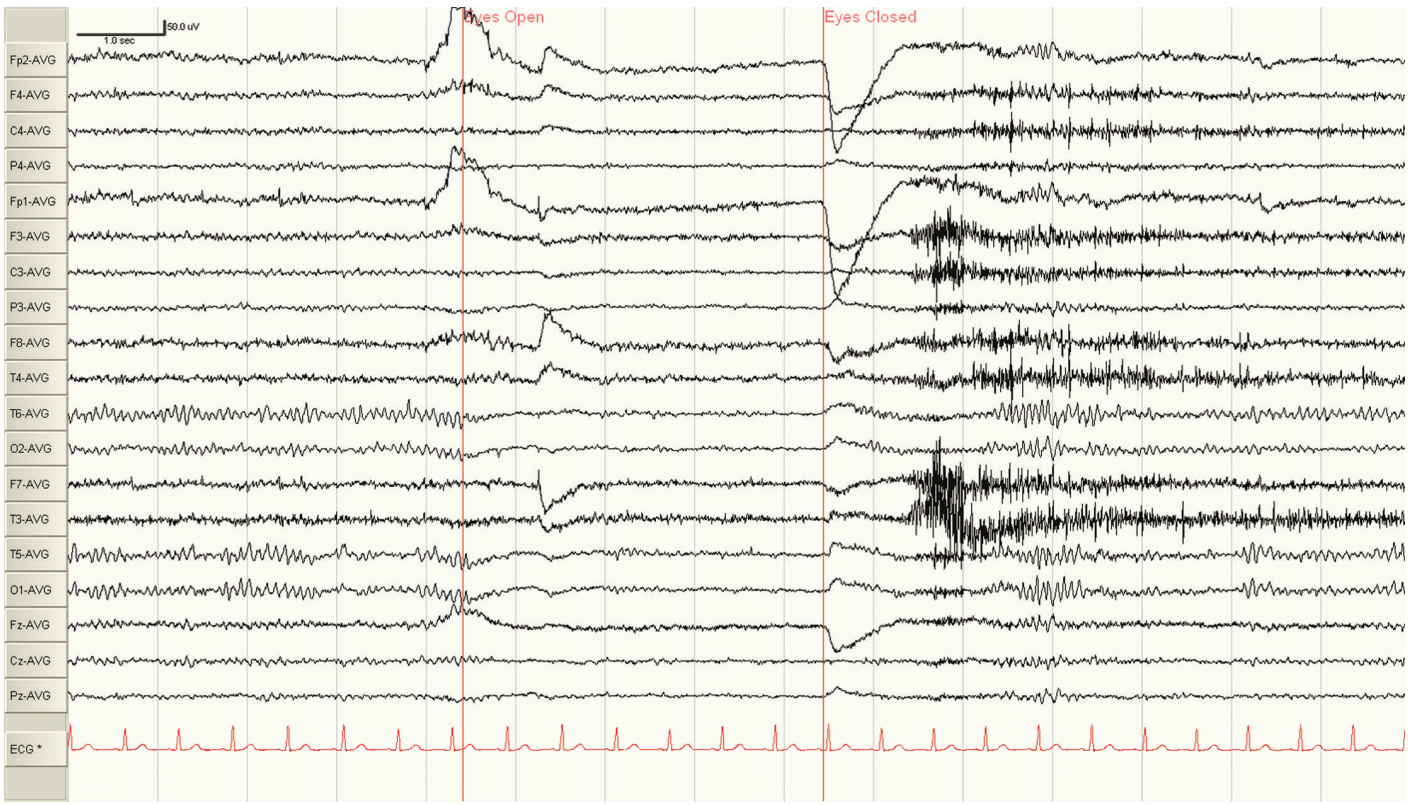

Fig. 82.3 Normal EEG demonstrating burst of alpha activity on eye closure.
Courtesy of Mr Robert Morris, Addenbrooke's Hospital, UK.

EEG and bilateral hippocampal sclerosis on MRI prior to temporal lobe epilepsy surgery. Invasive recordings are used prior to surgery for extratemporal lobe or non-lesional temporal lobe epilepsy. In addition, these electrodes can be of value to identify and delineate functional regions by using stimulation and recording of evoked responses prior to resective procedures for neocortical epilepsy near eloquent areas.

Subdural strips have electrodes in a single column while subdural grids are of different configurations and sizes with respect to the electrode arrangements. The electrodes are usually stainless steel however platinum electrodes that are non-ferromagnetic and hence MRI compatible are available but expensive. These methods only sample a limited brain region and preoperative planning is therefore important for placement of these electrodes. Depth electrodes are placed through special stylets inserted with neuronavigation or Robot-assisted techniques through burr or twist drill holes. These can have 4–10 contacts, but still record from a limited sampling area but is usually targeted to deep locations such as the insula, hippocampus, or amygdala. Bilateral placement from an occipital trajectory allows the electrodes to be orientated in line with the parahippocampal gyrus and multiple recording points are used to localize seizure activity in cases of medial temporal origin.

Subdural grids are placed via a craniotomy exposing the cortical surface with particular care used for interhemispheric or subtemporal placements due to the presence of subdural bridging veins. Grids can achieve a wider cortical coverage but provide more limited access to deep structures. Bilateral placement of subdural grids is not recommended. Although subdural strips can be placed through burr holes this is less safe than open craniotomy and misplacement is possible. SEEG and ECoG recordings can be combined by placement of both subdural grids and multiple depth electrodes in complex cases.

Nuclear imaging

When EEG, MRI, and seizure pattern are conflicting as to lateralization or lobar localization, or indeed in the presence of a normal MRI but compelling electrophysiological abnormalities, nuclear imaging in the form of an interictal FDG-PET scan or, if possible, an ictal single photon emission computed tomography (SPECT) scan can provide useful information.

FDG-PET determines regional cerebral glucose metabolism between seizures. Hypometabolism is typical of a cortical area that includes the seizure focus and left-right asymmetry can distinguish between true epileptogenic foci and regions such as both thalami which often demonstrate low glucose metabolism.

By contrast, ictal SPECT identifies cerebral hyperperfusion in seizure foci. It requires injection of a technetium tracer as early as possible after seizure onset before the seizure has spread. The tracer will fix in the brain in a concentration proportional to the blood flow at that moment. Image acquisition can be performed over the next few hours. The technical aspects of injecting a radio-labelled compound to a patient experiencing a spontaneous seizure within a few seconds of onset are extraordinarily challenging, making this a difficult and specialized investigation.

Both low-resolution studies are typically merged with an MRI to provide better resolution and anatomical localization.

Magnetoencephalography (MEG)

Magnetoencephalography is a promising technique where an array of multiple highly sensitive sensors is positioned over the scalp to detect small magnetic changes associated with the electromagnetic activity that underlies normal and epileptic EEG rhythms.

The electromagnetic dipole is calculated from numerous EEG interictal spikes and the dipole source viewed on a coregistered high-resolution MRI for anatomical correlation. Spatial resolution improves the greater the number of scalp electrodes used. The magnetic dipole is perpendicular to the EEG electrical dipole, so MEG will sometime detect activity missed on EEG such as seizures arising in the Sylvian fissure.

Medical management of seizures

See **Table 82.2** for the pharmacological properties of established anticonvulsants.

See **Table 82.3** for the pharmacological properties of newer anticonvulsants.

Phenytoin

Phenytoin was introduced into clinical practice as a non-sedating anticonvulsant in 1938 and very quickly became the drug of choice for most neurosurgeons in the treatment of acute seizures and status epilepticus largely due to its availability in intravenous form and its effectiveness in treating partial and tonic-clonic seizures. It does have a significant side-effect profile and is not effective against atonic or absence seizures.

Phenytoin exerts its action by binding to fast-inactivated sodium channels and holding them in their inactive state for longer which allows neurones to fire at moderate but not very rapid rates, limiting the generation and spread of action potentials. Phenytoin is metabolized by the liver, the first step of which process being mediated by the enzyme arene oxidase which has saturable (zero-order) kinetics within the therapeutic range. This means that the drug is eliminated at a constant rate, not related to the serum concentration. At low concentrations, phenytoin exhibits first-order kinetics where the elimination is proportional to the concentration. The concentration at which the shift in kinetics occurs varies with age. Thus, phenytoin has a narrow therapeutic range particularly at near-therapeutic doses, and any small change in dosing may result in disproportionate changes in serum concentration.

Phenytoin induces hepatic enzymes and may therefore reduce serum levels of other AEDs for instance valproate as well as lipid-soluble drugs like warfarin. Early, non-dose-related adverse effects include a skin rash in 5% of patients (this may rarely progress to a full-blown Stevens–Johnson syndrome). Neurotoxic dose-related side effects are uncommon at serum levels below 30 mg/litre. They typically present 8–12 hours after an oral dose and include asterixis, ataxia, dysarthria, nystagmus, and somnolence.

Chronic use is associated with reversible dysmorphic effects (acne, coarsening of facial characteristics, gingival hypertrophy, and hirsutism after several months) as well as osteopaenia (it antagonizes vitamin D), peripheral neuropathy, and cerebellar atrophy after years of treatment. Phenytoin is contraindicated in patients

Table 82.2 Pharmacological properties of established anticonvulsants

Drug	Primary mode of action	Indication (seizure type)	Absorption (bioavailability %)	Protein binding (% bound)	Elimination half-life (hours)	Route(s) of elimination	Target serum concentration
Carbamazepine	Sodium channel blockade	Partial, generalized	Slow (75–80)	80	24–48	Hepatic metabolism	4–12 mg/litre
Clobazam	GABAergic	Partial, generalized, epilepsy partialis continua	Rapid (90–100)	90	10–30	Hepatic metabolism	None
Phenobarbitone	GABAergic	Partial, generalized, myoclonic, status epilepticus	Slow (95–100)	50	72–144	Hepatic, 25% excreted unchanged	10–40 mg/litre
Phenytoin	Sodium channel blockade	Partial, generalized, status epilepticus	Slow (85–90)	90	24 (9–40)	Saturable hepatic metabolism	10–20 mg/litre
Sodium valproate	Multiple	Partial, generalized, absence	Rapid (100)	90	7–17	Hepatic metabolism	50–100 mg/litre

with second-degree heart block because of its lignocaine-like antiarrhythmic effect. It may also cause bone marrow suppression and an SLE-like syndrome. Its use in pregnancy is associated with the fetal hydantoin syndrome characterized by facial dysmorphism, cleft lip and palate, and cardiac defects.

Carbamazepine

Carbamazepine was first synthesized in 1953. It prevents repetitive firing of action potentials in depolarized neurones by blocking both use- and voltage-dependent sodium channels. Carbamazepine induces its own metabolism and can accelerate the hepatic breakdown of several lipid-soluble drugs, most commonly the oral contraceptive pill. Drugs that inhibit its metabolism resulting in toxicity include phenytoin and erythromycin.

It is an effective first-line agent for partial and tonic-clonic seizures, but it should be avoided in absences which it may exacerbate. It should be introduced at low doses and the dose increased very gradually to facilitate tolerance to its central nervous system side effects and to allow hepatic auto-induction to take place. Despite this, many patients do not tolerate the neurotoxic effects of the drug even at subtherapeutic doses.

Diplopia, dizziness, headache, nausea, and vomiting are the commonest signs of central nervous system (CNS) toxicity. Various idiosyncratic reactions can also happen, the commonest being a morbilliform rash seen in 5–10% of patients. Blood dyscrasias and toxic hepatitis are uncommon; a mild leukopenia is not unusual. At higher concentrations, carbamazepine has an antidiuretic hormone-like effect resulting in hyponatraemia which is usually asymptomatic. Like most anticonvulsants, carbamazepine is potentially teratogenic.

Oxcarbazepine

Functionally a prodrug, oxcarbazepine is rapidly reduced to its active metabolite in the liver. Like carbamazepine, it blocks sodium channels; it also modulates calcium and potassium channels. It has a similar spectrum of efficacy to carbamazepine and tends to be better tolerated with fewer neurotoxic side effects. A skin rash is less common but like its counterpart, it may rarely be associated with Stevens–Johnson syndrome. Hyponatraemia is more common. Oxcarbazepine does not appear to cause blood dyscrasias or hepatotoxicity. Furthermore, it has no effect on its own metabolism.

Table 82.3 Pharmacological properties of newer anticonvulsants

Drug	Primary mode of action	Indication	Absorption (bioavailability %)	Protein binding (% bound)	Elimination half-life (hours)	Route of elimination
Gabapentin	Calcium channel binding	Partial	Slow (60)	0	6–9	Not metabolized, renal excretion
Lamotrigine	Sodium channel blockade	Partial, generalized	Rapid (95–100)	55	22–36	Glucuronidation
Levetiracetam	Uncertain	Partial, generalized	Rapid (95–100)	<10	6–8	Non-hepatic hydrolysis, renal excretion
Oxcarbazepine	Sodium channel blockade	Partial, generalized	Rapid (95–100)	40	8–10	Hepatic conversion to active moiety
Pregabalin	Calcium channel binding	Partial	Rapid (90–100)	0	6	Not metabolized, renal excretion
Lacosamide	Sodium channel blockade	Partial	Rapid (95–100)	<15	13	Hepatic metabolism, 40% excreted unchanged
Zonisamide	Multiple	Partial, generalized	Rapid (95–100)	50	50–70	Hepatic metabolism, renal excretion

Gabapentin

Gabapentin was developed by adding a cyclohexyl group to GABA (gamma amino butyric acid, a major inhibitory neurotransmitter) which allows it to cross the blood brain barrier. Despite its structure, however, gabapentin does not bind to GABA receptors. Instead it binds to the alpha-2-delta subunit of the neuronal voltage-gated calcium channels, inhibiting calcium flow and neurotransmitter release from presynaptic terminals.

It is a useful adjunct in the treatment of partial seizures with or without secondary generalization and is also widely used for the treatment of neuropathic pain.

Adverse effects are mild and transient with ataxia, drowsiness, and nystagmus the commonest. Gastrointestinal symptoms such as flatulence and diarrhoea are occasionally reported and 5% of patients put on weight particularly at high doses. Gabapentin does not interact with other drugs as it is not metabolized by the liver, does not induce or inhibit hepatic enzymes, and is excreted unchanged by the kidneys.

Sodium valproate

Valproate exerts its antiepileptic action by limiting sustained repetitive firing by a use- and voltage-dependent effect on sodium channels. It also facilitates the effects of GABA. It is effective in idiopathic generalized epilepsies in particular and can be used across the complete spectrum of seizure disorders. It is metabolized by the liver but does not interfere with the hormonal component of the oral contraceptive pill. Because it does not exhibit a clear-cut concentration effect-toxicity relationship, routine therapeutic monitoring is unhelpful.

Unpleasant side effects include dose-related tremor, weight gain due to appetite stimulation, transient alopecia, and menstrual irregularities. Less commonly, thrombocytopenia and an insidious parkinsonism occur, both of which are reversible. Traditionally, patients undergoing neurosurgical intervention would have their valproate phased out prior to elective intervention because of the perceived haemorrhagic risk although this practice has now fallen out of fashion. Children under 3 years of age are at risk of hepatotoxicity, particularly when they have a concurrent metabolic disorder; rarely stupor and encephalopathy from hyperammonaemia can occur.

It should be avoided in women of childbearing age who are thinking of starting a family as it is associated with a 3% risk of neural tube defects, particularly at doses of more than 1000 mg a day.

Clobazam

Clobazam is a benzodiazepine that is a useful adjunct in the treatment of both partial and generalized seizures. It is also effective in children with Lennox–Gastaut syndrome. Like other benzodiazepines, it enhances GABA-mediated effects on chloride channels, binding to GABA-A receptors at the gamma subunit to increase the frequency of channel opening for postsynaptic inhibition. It is less sedative than diazepam. It is biotransformed in the liver to a number of metabolites.

Not all responders will maintain a worthwhile improvement in seizure control on long-term clobazam dosing because of the development of tolerance. This may be minimized with intermittent drug use. Side effects include depression, irritability, and lethargy. It may exacerbate pre-existing behavioural and mood disorders.

Phenobarbitone

The oldest anticonvulsant in common clinical practice, it was first synthesized in 1912 and enhances the effect of GABA by prolonging chloride channel opening at the GABA-A receptor, resulting in neuronal hyperpolarization.

Because of its propensity to cause sedation and behavioural problems, it has fallen somewhat out of fashion although its low cost and its effectiveness in treating seizure clusters and refractory status epilepticus ensure that it remains one of the most important AEDs in the developing world.

Phenobarbitone has a long half-life of 4 days; thus, dosing changes may take up to 3 weeks to achieve steady-state serum concentrations. It is metabolized by the liver and is a potent inducer of hepatic metabolism, accelerating the clearance of many lipid-soluble drugs. Side effects include agitation, depression, hyperactivity at extremes of age, an allergic skin rash, osteoporosis, and Dupuytren's contractures. It is teratogenic. Withdrawal seizures may occur unless it is tapered relatively slowly.

Lamotrigine

Lamotrigine is one of the most useful newer AEDs, effective across the complete range of seizure disorders. It is useful in patients with multiple seizure types, especially those with learning difficulties, possibly because its ability to reduce interictal spiking and it contributes to improved alertness.

Lamotrigine selectively blocks the slow inactivated state of the sodium channels thereby preventing the release of excitatory amino acid neurotransmitters, particularly aspartate and glutamate. It does not influence the metabolism of lipid-soluble drugs like warfarin or other AEDs.

When used as monotherapy, lamotrigine has a half-life of 24 hours. This drops to 15 hours when it is combined with enzyme-inducing agents such as phenytoin. Valproate inhibits the glucuronidation of lamotrigine, prolonging its half-life up to 60 hours. Withdrawing phenytoin therefore causes a rise in circulating concentrations of lamotrigine, while discontinuing valproate results in a fall in plasma lamotrigine levels. When used in combination with valproate, lamotrigine doses are routinely halved.

The risk of teratogenicity associated with lamotrigine monotherapy is low, making it the drug of choice in women of childbearing age wishing to conceive and unable or unwilling to discontinue AED use. Ataxia, diplopia, headache, insomnia, and tremor are sometimes reported. A self-limiting maculopapular skin rash occurs in 3% of patients on monotherapy (8% if combined with valproate). It is less likely the more gradual the drug titration regime with a reported risk of a severe skin reaction as high as 1 in 1000 adults.

Levetiracetam

Levetiracetam is an enantiomer of the ethyl analogue of piracetam whose exact mechanism of action is unknown. However, it is known to bind to synaptic vesicle protein 2A (SV2A) which is involved in synaptic vesicle exocytosis, mediating neurotransmitter release.

Its introduction represented a major breakthrough in epilepsy treatment, and it has quickly established itself as the most useful of all new AEDs. It is highly effective in all seizure types, is not

metabolized by the liver and thus has no significant drug interactions, does not require therapeutic monitoring, is often therapeutic at its starting dose and is generally well tolerated. Rare side effects include asthenia and psychosis, particularly in young males with a history of psychiatric illness and somnolence.

Status epilepticus

Status epilepticus occurs when a patient experiences continuous or repeated seizure activity without regaining consciousness for more than 30 minutes. It is most easily recognized as tonic-clonic or convulsive status epilepticus, which is a life-threatening medical emergency. A quarter of cases, however, are non-convulsive in nature, either absences or complex partial seizures that are diagnosed electrophysiologically.

Status epilepticus is most common in infants under 1 year of age and in adults over 65. The commonest causes are non-compliance with medication and withdrawal of existing anticonvulsant drugs in patients with known epilepsy. Alcohol, drug intoxication, and acute metabolic disorders are the most likely factors in patients presenting with new onset status.

Morbidity and mortality reflect the underlying cause and the physiological sequelae of prolonged convulsive activity including for example cardiac arrhythmias, circulatory collapse, hyperthermia, and hypoxia. The mortality of convulsive status epilepticus is around 10%, rising to 50% in the more physiologically challenged elderly population. Mortality is also higher the more acute the insult (e.g. acute cerebrovascular attack or trauma), while status epilepticus from alcohol intoxication or AED withdrawal carries a more favourable prognosis.

The aim of treatment is early termination to prevent neuronal damage caused by systemic and metabolic disturbances and by the direct excitotoxic effect of electrical discharges. The risk of lasting cerebral damage increases progressively if continuous convulsive status epilepticus persists for more than 30 minutes and particularly after 1–2 hours. This is because compensatory mechanisms to prevent brain damage are relatively satisfactory during the first 30 minutes but subsequently break down with increasing speed if the seizures persist unabated. Neuronal damage leads to transient or permanent neurological, epileptic, and cognitive sequelae if it does not prove fatal.

In practice, therefore, most authorities recommend emergent treatment if a seizure has lasted more than 5–10 minutes. Any delay worsens the prognosis and reduces the likelihood of seizures stopping without resorting to general anaesthesia. See Table 82.4.

Table 82.4 Treatment protocol for convulsive status epilepticus in adults

Stage (time)	Action
Stage I. 0–5 minutes *(suspected/impending status epilepticus)*	Diagnose SE or suspected SE by noting recurrent convulsive seizure activity without significant recovery of consciousness Establish and maintain airway Oxygenate (10 litre/min) Monitor vital signs Obtain IV access and start infusion (e.g. normal saline/dextrose saline) Investigate cause—draw blood for metabolic studies, AED levels, and toxic screen Consider early administration of antibiotics if infection is a possibility, thiamine in alcohol abuse or withdrawal, correct hypoglycaemia
Stage II. 5–10 minutes *(early status epilepticus)*	Administer a fast-acting benzodiazepine: 1. lorazepam 0.1 mg/kg at 2 mg/min IV OR 2. diazepam (shorter duration of action) 0.2 mg/kg at 5 mg/min IV Repeat once if seizure continues after 5 minutes Consider PR diazepam if no access—500 μg/kg to a maximum of 30 mg Consider midazolam 10 mg buccal as an alternative
Stage III. 10–30 minutes *(established status epilepticus)*	Introduce a longer acting anticonvulsant: 1. Phenytoin 15–20 mg/kg IV no faster than 50 mg/min in adults and 1 mg/kg/min in children; requires electrocardiogram (ECG) and blood pressure monitoring OR 2. Levetiracetam IV 30–70 mg/kg at 500 mg/min OR 3. Lacosamide IV 5–6 mg/kg at 40–80 mg/min
Stage IV. 30–60 minutes *(refractory status epilepticus)*	General anaesthesia in intensive care with EEG monitoring to achieve 'burst suppression' Review potential causative factors and reverse as indicated Consider intracranial imaging Consider 1. Phenobarbitone IV 20 mg/kg (100 mg/min) OR 2. Midazolam IV 0.2 mg/kg bolus followed by an infusion of 0.1–0.4 mg/kg/hour OR 3. Propofol IV 3–5 mg/kg bolus followed by an infusion of 5–10 mg/kg/hour OR 4. Thiopentone IV 2–3 mg/kg bolus followed by an infusion of 3–5 mg/kg/hour

Selecting appropriate patients for epilepsy surgery

The work up for epilepsy surgery aims to identify the relevant indications for surgery, in a stepwise fashion, such that seizures are effectively controlled with minimal resulting deficits.

- *Step 1: Confirmation of the clinical indications for surgery*

Establishment of the clinical diagnosis of epilepsy and the type seizures and in particular exclusion of pseudo-seizures is imperative. Adequate medical treatment must have been trialled and in particularly the patient must have been compliant with the medication regime. The impact of uncontrolled seizures on a patient and how much their quality of life is affected dictates whether to proceed with surgical treatment. As such the absolute frequency of seizures that necessitates surgery varies according the patient's view and their occupation. These factors require that an adequate period of time

has elapsed to establish that the seizures are sufficiently uncontrolled prior to consideration of surgery. A prolonged seizure history, on the other hand, may compromise the success of surgery as 'kindling' of further epilepsy foci may occur.

- *Step 2: Confirmation of the epileptic focus as the target for surgery*

Clinical evaluation of the semiology of the seizures, imaging, and surface EEG recordings are sufficient for the majority of cases. For mesial temporal sclerosis an MRI, ideally volumetric, in the correct coronal orientation or showing the appropriate signal changes such as on FLAIR sequences supplemented by EEG are sufficient for localization. For the latter, videotelemetry with surface EEG recordings in an inpatient setting after temporary withdrawal of anticonvulsants or even triggering of seizures is used for sufficient time to capture multiple seizures.

In cases where there is doubt regarding concordance between the imaging and electrophysiological investigations, such as interictal or ictal spikes originating from the contralateral side, then supplementary investigations are required. In practice an ictal SPECT (as described earlier) is most useful as interictal modalities can be less clear and ictal PET is impractical given the very short half-life of the radionuclide agent utilized.

More complex cases require invasive measures such as the placement of subdural grids and/or depth electrodes. These are used for extratemporal hemispheric epilepsy where the focus is accessible to a grid placed in the subdural space adjacent to the focus. Bilateral placement of depth electrodes may also be considered to capture the location or side of a seizure's origin in cases of hippocampal sclerosis. Foramen ovale (sphenoidal) electrode recordings after bilateral percutaneous placements are no longer widely used.

- *Step 3: Predicting and minimizing the resulting deficits following epilepsy focus resection*

Transfer of function away from the seizure focus does not always occur in prolonged epilepsy. There is variability in the extent of functional relocation and it will depend on the integrity of the contralateral hemisphere and alternative areas that can support the lost neurological function following resection. In cases of temporal lobe epilepsy ipsilateral to the side of speech, an amygdalohippocampectomy without neocortical resection will help preserve speech. Demonstration that memory and cognitive function can be provided by the contralateral side prior to an amygdalohippocampectomy is mandatory. f-MRI with memory algorithms will assess this prior to surgery and has largely replaced WADA testing in current practice.

Neuropsychological assessment evaluates cognitive function and helps preoperative planning to limit the deficits. It also identifies and helps to minimize the psychological impact of these procedures.

Surgical management of epilepsy

Johannes Schramm

Introduction

Surgical management of epilepsy is indicated in patients with drug-resistant epilepsy. As stated by the International League against Epilepsy (ILAE), drug-resistant epilepsy may be defined as failure of adequate trials of two tolerated and appropriately chosen antiepileptic drug (AED) schedules to achieve sustained seizure freedom (Kwan et al., 2010). In cases of catastrophic epilepsy of early childhood from severe brain malformations early surgery without AED trials for one or two years is possible. The aim is to resect the epileptogenic zone and a possible epileptogenic lesion. Palliative interventions aim to reduce seizure frequency.

Preoperative

History

Taking the history aims at describing seizure types (focal versus generalized), detecting loss of consciousness (simple partial versus complex partial), occurrence of auras, frequency and severity of seizures, and duration of the seizure disorder. Important hints regarding the epileptogenic zone can be obtained carefully exploring the semiology of the seizures. Precipitating events may have happened in the past history, such as early childhood febrile convulsions, brain injury, perinatal brain hypoxia, viral infections known to cause encephalitis, and need to be discussed with patient or parents. Careful history-taking is of utmost importance and the first step of presurgical evaluation.

Imaging

Imaging is primarily done by MRI, but PET and SPECT are also frequently employed. Since 'standard' cranial MRI examinations often fail to show epileptogenic lesions, it is advisable to follow a special MRI examination protocol for cases of pharmacoresistance (Wellmer et al., 2013). These authors propose six essential MRI sequences (FLAIR, T2-weighted, T1-weighted, haemosiderin/calcification-sensitive sequences). Slice thickness for T2 and FLAIR must not exceed 3 mm. T1 images should be acquired in three-dimensional technique at 1 mm isotropic voxel size. For T2 and FLAIR, at least two slice orientations each must be demanded in hippocampal angulation. If a lesion other than hippocampal sclerosis is detected, T1 weighted sequences before and after the injection of contrast are performed (Wellmer et al., 2013). The value of MRI can be enhanced by using fMRI techniques, and morphometric analysis of 3D T1 weighted images for language lateralization and visualization of functionally important whiter matter tracts (Urbach et al., 2015). SPECT is particularly useful as ictal SPECT (i.e. with the radioactive tracer injected after the start and during a seizure). Ictal SPECT identifies areas with ictal hyperperfusion, which is considered a surrogate for the epileptic zone. Depending on the timepoint of injection this technique may more show the area where the seizures propagated into, less the area where they originated from. PET using [18F] fluorodeoxyglucose demonstrates areas of glucose hypometabolism, thought to be concordant with the epileptogenic zone. The technique may be particularly useful in patients where MRI did not show a lesion but a well-defined PET-positive area in the temporal lobe (Carne et al., 2004). The WADA-test consists of an intracarotid amobarbital injection, rendering one hemisphere non-functional for 4–5 minutes, thus lateralizing language dominance. Current use is mainly in candidates for hemispherotomy and callosotomy. In the latter it serves to rule out transposition of either the motor or sensory speech area to the contralateral hemisphere which might have negative consequences if total callosotomy is planned.

Electroencephalography (EEG)

EEG recordings in surgical candidates are indispensable and are performed different from routine EEGs. Recordings with up to 68 channels are typically done in a specialized suite with continuous video surveillance in split-screen technique. Seizure semiology can thus be directly related to the EEG curves shown simultaneously on the same screen. Presurgical video-EEG is done after withdrawal of AED in order to record typical seizures, hoping to get localizing hints about seizure origin. Depending on congruent findings from MRI imaging and video-EEG it may be possible to go forward with planning a resection. In case of incongruent findings or overlap of ictal activity with eloquent cortex, the video-EEG may serve as the basis for planning the insertion of deep electrodes or subdural plate electrodes. In case the ictogenic lesion and/or the ictogenic zone is close to or overlapping with eloquent cortex the implantation of a larger grid-electrode may be necessary, since this can also

be used to map eloquent cortex extraoperatively in the awake patient. Extraoperative mapping with a grid has the advantage that not only functional cortex can be mapped but also seizures can be recorded from the same grid, whereas in awake surgery the recording of seizures cannot usually be counted on. Depth electrodes are inserted using stereotactic techniques and can reach tiny lesions at the bottom of a sulcus or in deeper parts of the cortex difficult to reach with subdural electrodes. Depth electrodes, subdural strips, and grids may be used in combination.

Epilepsy surgery

Epilepsy surgery is usually performed in an epilepsy surgery centre by an epilepsy surgery group and is the penultimate example of multidisciplinary teamwork. In most epilepsy surgery centres the presurgical evaluation is in the hands of the epileptologists and paediatric epileptologists whose main task it is to identify drug-resistant cases and within that group to identify surgical candidates. Part of the team is the neuropsychologist whose tests may point to certain areas of the brain related to cognitive deficits and the neuroradiologist. It is ideal when one neuroradiologist and one neuropathologist is specialized in dealing with the epilepsy surgery cases. Cases are finally discussed in the epilepsy surgery conference where the clinical epileptologist, the electroencephalographer, the neuroradiologist, and the neurosurgeon discuss each case with the aim of forming a hypothesis where seizures originate from, whether there is a lesion and what the significance of that lesion for this epilepsy is and finally what type of resection should be performed. Teamwork is essential as an absolute prerequisite and also for the after-care, management of side effects, the follow-up, and potential decisions on how to handle persisting seizures.

Surgical treatment of epilepsy

Epilepsy surgery comprises a spectrum of interventions, classically divided into temporal and extratemporal resections. See Table 83.1. One can also differentiate between resective and disconnective surgeries since disconnecting an epileptogenic area completely from the surrounding brain, no seizure activity can be conducted. Classic examples are callosotomy or hemispherotomy. Another group is palliative epilepsy surgery, in which complete seizure freedom can rarely be achieved, the aim being a marked reduction in seizure frequency. Palliative techniques are usually employed when resections are impossible, as in multiple subpial transections in eloquent cortex. Some palliative procedures use augmentative techniques (vagal nerve stimulation, deep brain stimulation).

Lesionectomies

Lesionectomies come in three forms: pure lesionectomy, lesionectomy with rim, and extended lesionectomy. Common lesions are vascular malformations, tumours, and focal cortical dysplasias. Whenever possible a total lesionectomy is attempted.

A pure lesionectomy is done when no seizure activity originated away from the lesion and when eloquent cortex does not allow to include a rim. A lesionectomy with rim is the preferred procedure in non-eloquent brain areas. An accepted hypothesis is that seizures originate from the cortical area which borders on the lesion. Based on this hypothesis a common resection technique for lesionectomy is to remove the lesion proper with a rim of surrounding cortex which may arbitrarily be defined (e.g. 1 cm or until next pial layer). In clinical practice a lesionectomy in non-eloquent cortex will usually be performed including the small rim of cortex around it, including deeper lying cortex around a sulcus. Occasionally this rim may be a bit more extended intraoperatively, guided by discoloration, abnormal cortex consistency, or gliotic changes in the immediate vicinity of the lesion. In cavernomas it is safe to assume that in most cases seizures will originate from the haemosiderotic cortical rim around it.

The situation is more complicated when the presurgical evaluation demonstrated an epileptogenic zone extending well beyond the immediate perilesional cortex (Fig. 83.1). How precisely could the epileptogenic zone around or close to the lesion be defined, and therefore how much epileptogenic cortex should be removed together with the lesion for an extended lesionectomy? The combination of lesionectomy plus corticectomy may consist of partial temporal lobectomy or of temporolateral lesionectomy combined with mesial amygdalo-hippocampo-parahippocampectomy. In ETL surgery an extensive variant of extended lesionectomy is a lobectomy or even a multilobar resection. In a recent large cavernoma series with pharmacoresistant epilepsy extended lesionectomies were necessary in 87% of 76 cases (von der Brelie et al., 2013). In the same series seven of 37 lateral neocortical cavernomas were resected together with mesial structures. Defining extent of resection

Table 83.1 Epilepsy surgery spectrum

Bonn University Epilepsy Surgery Group, Germany, 1989–2011

Type of procedure	Absolute numbers		Relative numbers
All therapeutic procedures	2590		100%
Temporal resections	1485		57%
AHE	715		48%
Trans-Sylvian		544	
Transcortical		77	
Subtemporal		72	
ATL	348		24%
With hippocampectomy		321	
Without hippocampectomy		39	
Lesionectomy	345		23%
With hippocampectomy		121	
Without hippocampectomy		224	
Reoperation/extension	65		4%
Extratemporal resections	456		18%
Frontal		289	
Other		167	
Disconnection:			
hemispherotomy/callosotomy	196		7.5%
MST alone	28		1.1%
(MST add-on)	108		
VNS	425		16.4%

AHE, amygdalohippocampectomy; ATL, anterior temporal lobectomy; MST, multiple subpial transection; VNS, vagus nerve stimulator implantation.

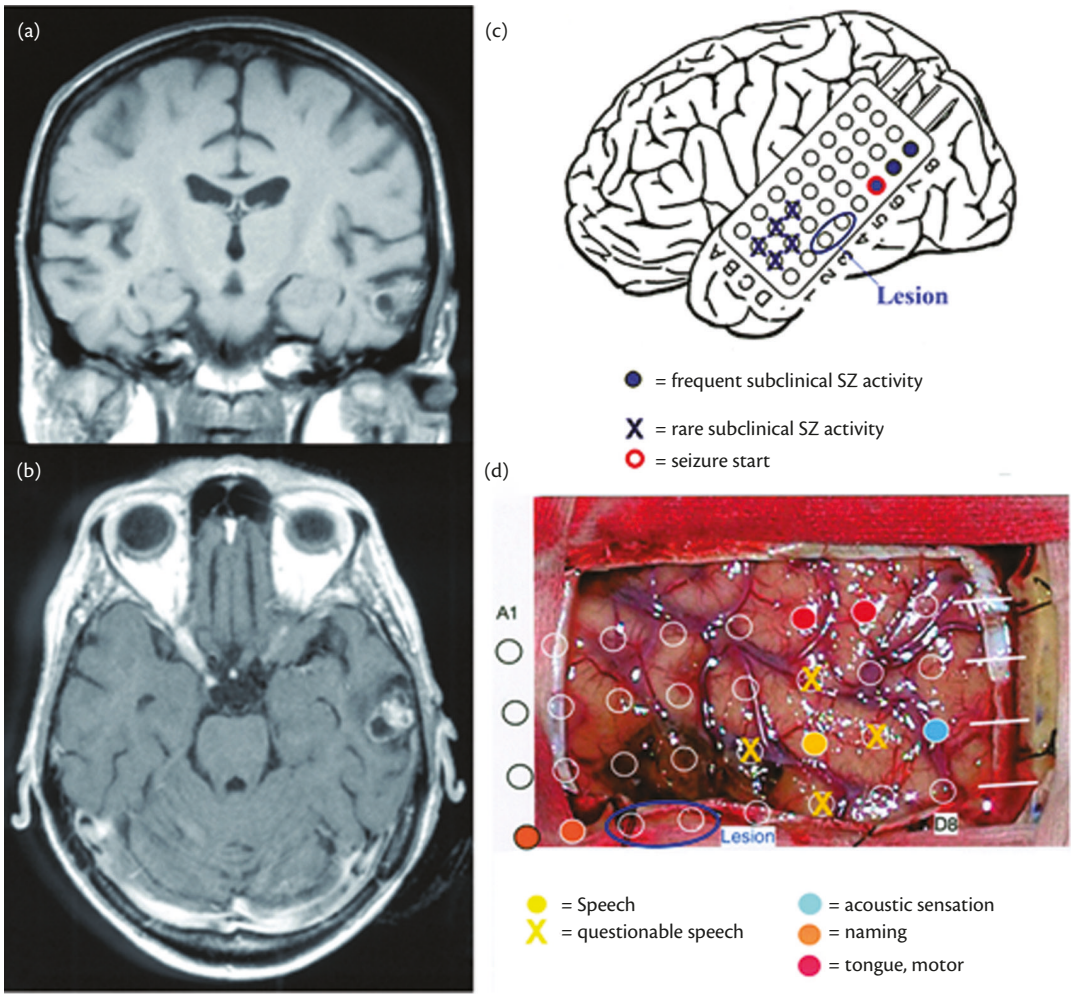

Fig. 83.1 Extended temporo-lateral lesionectomy for left-sided cavernoma. (A, B) MRI images of cavernoma in middle temporal gyrus. (C) Schematic drawing of implanted grid-electrode showing the location of frequent subclinical seizure activity in bottom row posterior to the lesion rare subclinical seizure activity in rows C and B anterior to the lesion as well as location of the seizure origin. The grid was implanted because of the proximity to the presumed speech area and the widespread ictal activity. The drawing is the result of extraoperative mapping. (D) Brain surface with position of electrode contacts shown by circles. The functional results of mapping are described next. The site of the lesion is shown by a blue ellipse and above that the dark area is the haemorrhagic cortex. Using the image from the ictal recordings in C together with the functional results from D it is clear that the seizures start well posterior from the haemorrhagic cortex and the subclinical seizure activity is also far away. The extended lesionectomy included contact B1–3, C1–5, and D1–8. The patient had no speech deficit after surgery

for extended lesionectomies frequently requires invasive presurgical evaluation with strips and grids, especially when eloquent cortex is close. Electrocorticography during surgery is used by some groups to define extent of resection, but of questionable usefulness, since no seizures are recorded, only interictal spikes. It is better to base decisions on ictal recordings (Rostomily and Silbergeld, 2006).

Temporal procedures

Choice of procedure for temporal lobe epilepsy (TLE) depends on type of TLE: mesial temporal lobe epilepsy (MTLE), lateral neocortical TLE, and temporal lobe epilepsy. Neocortical TLE is the rarest type (Walczak, 1995) and usually corresponds to a lesionectomy or an extended lesionectomy, leaving mesial structures behind. MTLE is characterized by seizures originating from the hippocampal/parahippocampal region. Temporal lobe epilepsy without further specification involves both mesial and cortical structures of the temporal lobe. Thus, temporal lobe resections come in three main versions: anterior temporal lobectomy (ATL), lateral neocortical resection, selective amygdalohippocampectomy (SAH). The pure mesial resection in SAH can be done by three approaches: transcortical (Olivier, 2000), trans-Sylvian (Yasargil et al., 1985), and subtemporal (Hori et al., 1993). See **Figure 83.2**. Many groups use ATL (synonym: anterior two-thirds lobectomy) or a combined resection of the temporal pole with extended mesial resection (synonym: cortico-(unco-)amygdalohippocampectomy) also for mesial TLE. The only prospective randomized study comparing drug treatment with surgery was performed for temporal lobectomy and proved surgery to be superior to medication treatment (Wiebe et al., 2001)

ATL is the classic resection type for TLE and by many groups used as a standard TLE procedure. It includes removal of the temporal lobe 5–5.5 cm backward from the temporal tip in the nondominant hemisphere and 4.5 cm in the dominant lobe. The extent of mesial resection can reach more posteriorly than the plane of

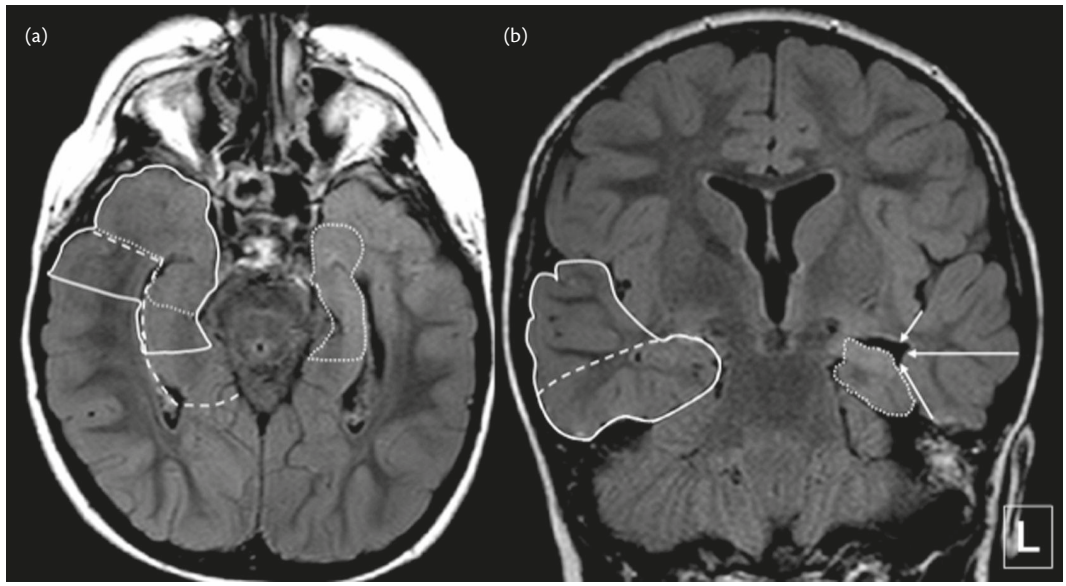

Fig. 83.2 Outline of resection types used for TLE surgery. (A) Axial MRI showing three typical resection types on the right side: Pole resection plus SAH (dotted line), pole resection combined with extensive HC-PHG resection (dashed line), standard anterior temporal lobectomy including mesial resection (solid line). In the left hemisphere the typical resection volume for SAH is outlined. (B) On the coronal MRI the outline of standard ATL is shown (solid line) and the posterior part of pole resection plus extensive amygdylohypocampectomy (AHC) (dashed line). On the right side of the MRI cut the three approaches to the mesial resection of SAH are indicated by arrows. On the left MRI side, the resection is outlined by dashed line.

neocortical resection. As a variation some groups leave the superior temporal gyrus (STG). Via a pterional craniotomy which also exposes about 2 cm of the frontal lobe and the STG and middle temporal gyrus (MTG) the distance to the resection plane is measured from the temporal tip over MTG. As the first of two steps the lateral and basal neocortical tissue block is removed first including the pole, with the second step the removal of the uncus, hippocampus, and parahippocampus. The pia is opened parallel to the Sylvian fissure over the STG and vertically down to the base (**Fig. 83.3**A). The temporal pial layer over the Sylvian fissure is not removed (**Fig. 83.3**B), when transecting the cortex and white matter of the neocortex, one will enter into the temporal horn and with the help of the cavitron ultrasonic surgical aspirator (CUSA) the temporal horn is opened anteriorly to its tip. The STG tissue between this opening and the Sylvian pial layer is removed until one reaches anteriorly the mesial arachnoid of the temporal pole. The neocortical block is still attached to the mesial structures at the base of the temporal lobe. The remaining attachment of the neocortical block is disconnected with the CUSA working laterally and parallel to the hippocampus/parahippocampal gyrus (HC-PHG) in a posterior-anterior direction until the pial cut on the mesial anterior pole area is met. Anterior to the choroidal point the amygdaloid body is bulging in a basolateral direction and can be removed with the ultrasonic aspirator. The choroidal fissure, choroid plexus, and fimbriae are easily identified. The fimbriae along the choroidal fissure are detached with a dissector. The uncus is emptied and the amygdalum removed including the tissue bridge between the head of the hippocampus and the amygdalum, which corresponds to the entorhinal cortex. The greater part of the hippocampal head can be removed, so the HC body is now detached laterally and anteriorly. When removing the amygdalum with the CUSA problems are avoided if a line drawn mentally from the choroidal point to the limen insulae is not crossed mesially. The CUSA is acting directly on the thin arachnoid layer of the mesial temporal lobe which is covering the vessels going around the brain stem, the third nerve, and the peduncle. By carefully choosing the right CUSA setting it is usually possible to not open the mesial arachnoid, except for small children.

The HC-PHG block is still attached mesially to several small arteries covered by a double layer of pia mater which enter the hippocampal sulcus from a mesial to a lateral direction. In theory it would be possible to use the CUSA and just remove the superficially located HC and the PHG below the vascular pedicle of the hippocampal sulcus. If one wants to obtain a good specimen of the hippocampal structure, *en-bloc* removal is aimed for. By elevating the fimbriae, the double layer of pia mater covering the arteries in the hippocampal sulcus can be visualized. The combined HC-PHG block can then be disconnected posteriorly using the CUSA, leaving the vessels in the hippocampal sulcus with their double pial layer as residual attachment. A final step is to open the pia mater along the choroidal fissure to gain access to the vessels which are coagulated preferably inside the hippocampal sulcus and cut. Then the lower second pial layer of the hippocampal sulcus is also cut. Mesially and mesiobasally, the layer of pia mater over the PHG is left intact and using a dissector the PHG is detached from its pia mater and mobilized in a lateral direction out of its pial bed. Usually, a 15–20 mm segment of combined hippocampus and parahippocampus can be obtained. In the majority of cases the mesial pial layer over the brainstem and the vessels can be preserved. Bipolar coagulation is only used on the small arteries in the sulcus which need to be cut a short distance away from the larger arteries going around the brainstem. Oxidized cellulose usually takes care of minor bleedings from the exposed pial layers.

A popular alternative to a standard resection for TLE is the combination of a temporal pole resection with more posteriorly extended resection of mesial structures. (synonyms: Spencer-type resection, cortico-(unco-)amygdalohippocampectomy). This approach is used

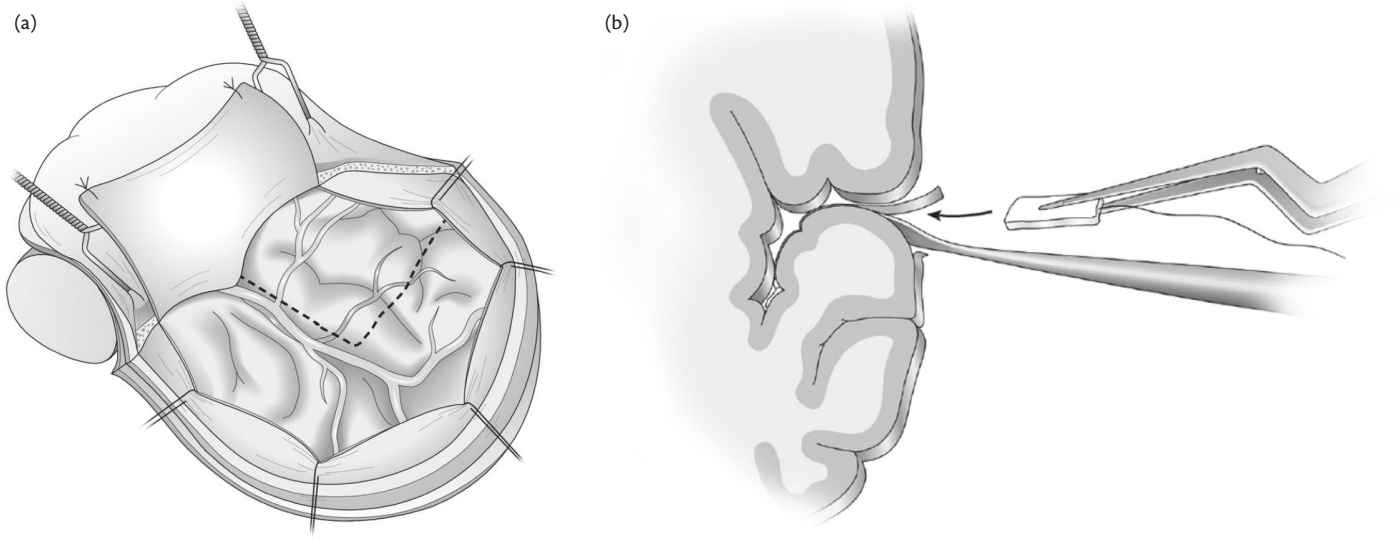

Fig. 83.3 (A) Schematic drawing of craniotomy for right-sided standard anterior two-thirds temporal lobectomy. The dotted line indicates the pial incision. (B) Schematic drawing where to develop the subpial plane on the superior temporal gyrus very close to the Sylvian fissure in order to preserve the pial layer overlying the arteries in the Sylvian fissure.

in some centres as the standard approach for temporal lobe epilepsy but it also very useful if a small lesion (e.g. cavernoma or benign tumour) is located in the pole, in the amygdalum, or in the head of the hippocampus.

After a craniotomy similar to standard ATL the temporal pole is resected about 3 cm behind the polar tip. Pia is opened parallel to the Sylvian fissure and vertically down to the base. Using the CUSA one reaches the base of the temporal lobe and passing through the white matter the tip of the temporal horn is opened. Leaving the arachnoid over the middle cerebral artery intact, the uncus is emptied, and the head of the hippocampus with the amygdalum opposite is exposed. In order to reach further backward to increase extent of mesial resection, the cut surface of the temporal lobe is retracted posteriorly above the level of the opened temporal horn. The combined block of HC-PHG now needs to be mobilized laterally, posteriorly, and mesially. The anterior disconnection consists of removing the bulging major part of the amygdalum and most of the hippocampal head with the attached entorhinal cortex. The lateral disconnection is best performed by a CUSA, or bluntly with a dissector, posterior disconnection can be done with a CUSA or bipolar and suction. Mesial disconnection is achieved similar to the steps described for ATL.

Selective amygdalohippocampectomy (SAH) is considered an adequate or even ideal resection type for mesial TLE, typically caused by ammonshornsclerosis (synonym: mesial temporal sclerosis, hippocampal sclerosis). It can also be used for small lesions in these mesial structures, posterior to the choroidal point. Three approaches exist: trans-Sylvian, transcortical, and subtemporal.

A pterional craniotomy is used for trans-Sylvian SAH (Yasargil et al., 1985), which should expose about 2 cm of the frontal lobe and 3 cm of the temporal lobe. The Sylvian fissure is opened. The MCA is dissected carefully to expose the inferior circular sulcus in its first 15–20 mm behind the limen insulae (Fig. 83.4). The next step is opening of the temporal horn via an incision in the inferior circular sulcus reaching about 15 mm backward from the limen. Dissecting with bipolar coagulation through the temporal stem in a slightly basolateral fashion one should reach the ventricle after about 12–15 mm (Fig. 83.5). This opening of the ventricle is then enlarged towards the tip of the temporal horn, first working around the supero-medial bulging amygdalum. Inside the ventricle the choroidal plexus, the choroidal fissure, and the choroidal point are identified. Outside the ascending M1 can be seen and the next step is emptying the uncus, carefully leaving the mesial arachnoid intact. The fimbriae are then detached and

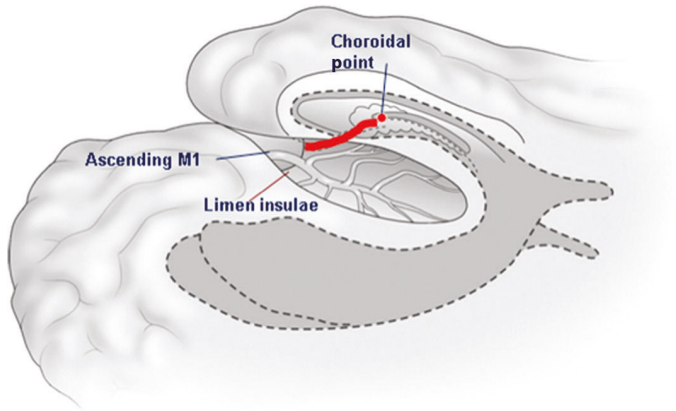

Fig. 83.4 Schematic drawing of right trans-Sylvian approach to expose insular cortex and MCA branches with projected outline of temporal horn, choroidal point, and limen insulae. The red line describes the most mesial extent of the resection, and after opening of ventricle is mentally drawn between the limen insulae and the choroidal point. Working anterolateral and along this line, no adverse effects have to be feared, resecting the amygdalum and the head of the hippocampus. This is an important landmark when dealing with small tumours in the head of the hippocampus.

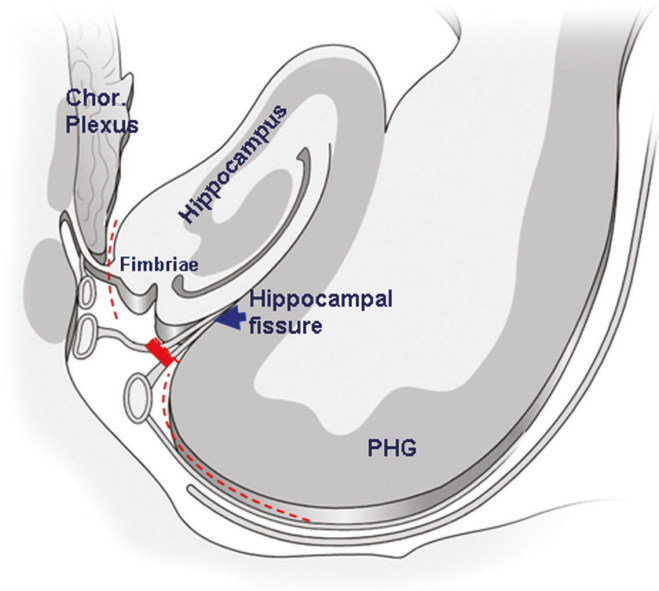

Fig. 83.6 Schematic drawing of coronal section of the mesiobasal structures of the left temporal lobe. The HC, PHG, and the hippocampal sulcus are shown, with the solid red line indicating the area where the small vessels in the hippocampal fissure are transected. The shorter dotted line shows the area where the fimbriae can be elevated with the blunt dissector and the longer dotted red line is outlining the subpial plane between the tissue of the PHG and its pial mesiobasal layer.
Courtesy of Isabelle Christensen and Johannes Schramm.

anterior to the choroidal point the bulging amygdalum is removed with a CUSA and the mesiobasal tissue bridge between the amygdaloid body and the hippocampal head is also removed with a CUSA, this disconnection leading directly into the emptied shell of the uncus. Again, one works directly on the mesial arachnoid, the CUSA setting must be appropriate. At this stage, the HC-PHG block is detached mesially. Posterior disconnection is then done with a CUSA, followed by lateral disconnection either with a dissector or a CUSA leaving the basal pia intact. The central part of hippocampal body with PHG attached can now be detached from its pial cover after having cut the two pial layers which encase the vessels and the hippocampal sulcus (see Fig. 83.6). In this way an *en-bloc* specimen of combined HC and PHG can be obtained, allowing precise histological diagnosis and analysis for scientific purposes, having obtained permission from each patient.

A lateral transcortical or trans-sulcal approach can also be used for SAH (Niemeyer, 1958; Olivier, 2000). A linear incision and a smaller craniotomy suffice. It is not easy to find the ventricle, so navigation is useful. The opening in the cortex is about 15 mm in anteroposterior (AP) direction. It is advantageous to enter the ventricle low and not to injure the roof of the temporal horn since there the fibres of Meyer's loop are located. The detachment and mobilization of the HC-PHG tissue block is performed from a different perspective but following the same principles as in trans-Sylvian SAH (i.e. leaving the mesial arachnoid intact and cutting the vessels in the hippocampal sulcus). One should also empty the uncus and remove the larger part of the amygdalum in this approach.

The third approach variant for SAH is via the subtemporal route (Hori et al., 1993; Park et al., 1996). It is usually done via a linear incision and a small very basally located craniotomy. Mesial structures can be reached via various pathways, through the fusiform gyrus, or via the PHG or via the collateral sulcus. For this the temporal lobe needs to be elevated, occasionally made difficult by basal temporal veins. In that case the basal pia of the inferior temporal gyrus is opened, and the cortex is elevated leaving the pia behind on the temporobasal dura. In rare cases a small tunnel through the ITG is created with a CUSA not higher than about 8–10 mm which significantly improves the ability to elevate the rest of the temporal lobe without damage to basal veins. It may be difficult to find the ventricular lumen and the coronal MRI will clearly show the distance the surgeon has to go underneath the temporal lobe (approximately 22–25 mm) before dissecting obliquely upwards through the cortex to reach the ventricle. Having entered into the ventricle this transcortical incision is elongated so one has a better overview over the content of the ventricle and can identify the landmarks (fimbriae, choroidal point, amygdala bulge). The HC head, the entorhinal cortex, and the amygdalum are removed with a CUSA followed by emptying the uncus. The HC-PHG block is then mobilized in a similar fashion as described for the transcortical and trans-Sylvian approach.

Lateral neocortical temporal lobe resections are usually performed for a lesion. They may be necessary as a lesionectomy with rim, or an extended lesionectomy including an area of adjacent cortex. In rare cases a larger block of lateral neocortex may be removed. The craniotomy does not need to reach above the Sylvian fissure for more than a few millimetres. A curvilinear or question-mark incision is used depending on how far posterior the lesion is located. Especially in dorsally located lesions a grid may have previously been used to map language-relevant cortex. The principle requires that all cortical tissue under the designated surface area be

removed including the cortex at the bottom of the sulcus. This can easily be done with a normal sucker or a CUSA. Dorsolateral temporal lobe lesionectomies are the only area where awake craniotomy can be helpful to locate language-relevant cortex. Larger arterial branches or the vein of Labbé need to be spared, and the resection must not extend into the white matter of the temporal lobe in order to spare the optic radiation.

Vagal nerve stimulation (VNS)

The implantation of a vagal nerve stimulator is a palliative procedure with the aim to reduce the frequency of seizures in drug-resistant patient. It is only indicated after a proper epileptological evaluation, ideally presurgical evaluation, which did not result in the detection of an operable epileptogenic lesion or zone. In case of medically refractory epilepsy and a resectable lesion, the resection should always be preferred to VNS implantation because it has the potential to cure the epilepsy. VNS is currently used for generalized and partial seizures and in many studies a greater than 50% reduction of seizure frequency in over 50% of the patients can be achieved. In some long-term studies an increase in the reduction of seizure frequency from over 50% to 70–80% has been described (Spanaki et al., 2004; Uthman et al., 2004). VNS is used in adults and the paediatric population, provided body size can accommodate the pulse generator, the current model being 45 × 32 × 7 mm. As a positive side effect, improvements in quality of life have been documented after VNS implantation (Cramer, 2001; Spanaki et al., 2004).

Extensive scarring after previous left-sided neck surgery constitutes an exclusion criterion. During surgery monopolar diathermy cannot be used, only bipolar.

A VNS set consists of a pulse generator, a lead with the helical vagus electrodes and a programming unit. A hand-held programmer covered by a sterile bag during surgery, held over the pulse generator can wirelessly set the stimulus parameters.

The patient is positioned and draped for two left-sided incisions, one at the neck below the level of the carotid bifurcation and one in the anterior-axillary line for the creation of an infraclavicular subcutaneous pocket. The left side is chosen because the left vagus nerve contains less nerve fibres going to the atrium than the right one. The vagus nerve runs with the carotid artery and jugular vein and should be freed from the connective tissue sheath for approximately 3 cm. The cervical end of the connection cable has three helical structures: two electrodes and one anchor. The highly flexible helices are placed around the vagus and anchored to deeper fascial layers with two plastic anchors, avoiding muscles which might move. See **Figure 83.7**.

A third of these anchors is used to fix the cable more superficially but underneath the platysma. From a short incision in the anterior-axillary line a subcutaneous pocket is formed over the pectoralis fascia, large enough to bury the pulse generator so that the suture line is circa 2 cm away from the pulse generator. The tunnelling instrument provided in the VNS set is used to pull the cable from the cervical incision down to the infraclavicular pocket. Cable loops should be formed and placed in the generator pocket away from the skin incision in order to avoid damage when generator replacement becomes necessary. The generator is placed with the inscription on top and fixed in the depth of the pocket with a single suture through a hole provided for that purpose. Older models of the generator may have different connector sockets and details should be looked up in the manual of the manufacturer. Before definitely closing the wound an intraoperative testing of the lead is performed, testing impedance of the electrodes and a test stimulation can be performed. The wounds are closed in two layers.

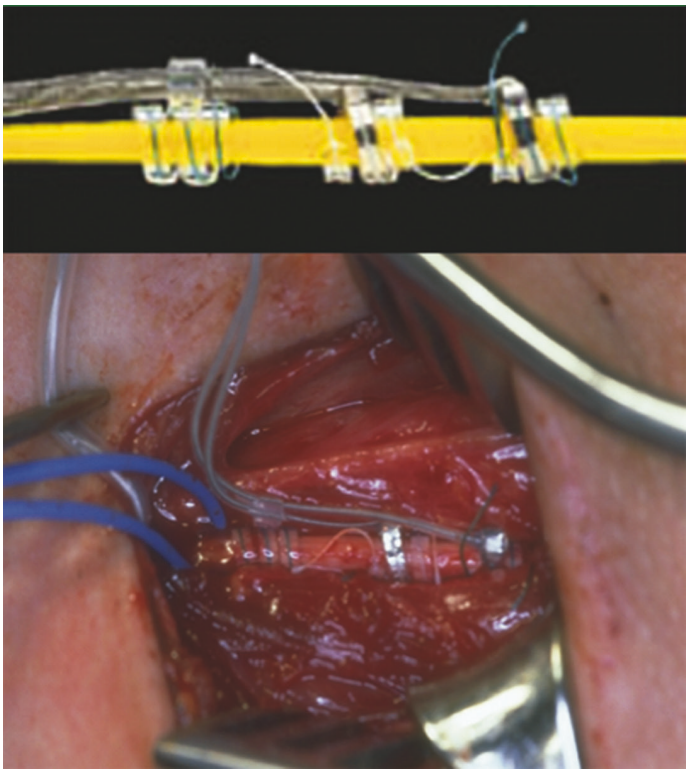

Fig. 83.7 VNS electrode sample and implant.

In rare cases a subpectoral implantation may be preferred (e.g. in patients with very little or no subcutaneous fat). Modern generator models have a battery life of 5–8 years, depending on stimulus parameters. Stimulation can begin immediately after the surgery, although many groups prefer to wait some time before stimulation is initiated. Patients are provided with a magnet which stops the stimulation when held directly over the implanted pulse generator until the magnet is removed. This may be useful for patients who have a hoarse voice during stimulation periods and want to sing or need to speak in public. The magnet can be swiped over the pulse generator to trigger an on-demand stimulation, which some patients use when they feel an aura is preceding a possible seizure. MRI head scans are possible while the generator output is programmed to 0 mA during the scan. Stimulation parameters vary but usually a short period of stimulation is followed by longer silent period. Details can be looked up in the VNS physicians' manual.

Hemispherectomy/hemispherotomy

The indication for this procedure is established for unihemispheric lesions causing intractable seizures. This hemispheric damage is usually associated with some degree of hemiparesis, frequently cognitive impairment, and hemianopia. In cases of catastrophic epilepsy in small infants where drug treatment is known to not work, very early surgery in the first months of life may be indicated. Ideally all seizures should originate in the affected hemisphere.

Classic anatomical removal of one hemisphere was largely replaced by surgery types with less tissue resection and more disconnection such as Rasmussen's functional hemispherectomy (Rasmussen, 1983). The trend to replace resection by more disconnections has evolved during the last 25 years using the terms hemispherotomy and hemispheric disconnection or deafferentation. For Rasmussen's functional hemispherectomy, functionally equivalent to anatomic resection, only a large temporal lobe resection and a large central resection is done, the rest is disconnected but remains *in situ*. The less tissue is removed the more the term hemispherotomy is justified and this includes the dorsal transcortical subinsular hemispherotomy (Delalande et al., 2007) the trans-Sylvian-transcortical-transventricular keyhole hemispherotomy (Schramm et al., 2001) and the perisylvian window technique (Villemure and Mascott, 1995), and related techniques (Shimizu and Maehara, 2000). For clarity one should restrict the term hemispherotomy for those procedures where very little brain is removed.

The advantage of the modern hemispherotomies is a marked shortening of surgery time, a significant reduction in blood loss, a reduced necessity for blood transfusion, a smaller extent of exposure with a reduced incidence of intraoperative problems. These advantages are significant in small infants and babies, but also welcome in older patients.

Common structural lesions of the hemisphere are inborn developmental defects (hemimegalencephaly, multilobar dysplasias, and others), Sturge-Weber syndrome and acquired lesions (perinatal infarctions or haemorrhages, Rasmussen's encephalitis, or post-traumatic and postencephalitic damage).

Occasional contralateral seizures or bilateral epileptogenic activity is not an automatic contraindication as satisfying rates of seizure freedom are possible (Doring et al., 1999). Indicating hemispherotomy and finding the right time-point is difficult and sometimes problematic, especially in Rasmussen's encephalitis when the dominant hemisphere is affected.

Surgical techniques

Hemispherotomies are technically demanding especially in cases of hemimegalencephaly or extensive holohemispheric dysplasia. The modern hemispherotomy procedures have in common that the callosotomy is done from within the ventricle, with ventricular access achieved by opening the Sylvian fissure or creating a window through the operculum. The disconnection of the frontal, temporal, and occipitotemporal lobe is also done through this exposure. Various modifications have been used (Devlin et al., 2003). See **Figure 83.8**. The dorsal transcortical approach is also using the transventricular route to disconnect the hemisphere from its neocortical mantel (for more detailed descriptions, see Schramm, 2002), alternative techniques, such as hemidecortication are used less commonly.

Rasmussen's functional hemispherectomy needs a large craniotomy exposing the central part of the hemisphere including all of the temporal lobe. It includes removal of the temporal lobe and a large central supra-Sylvian block of cortex (about 7–8 cm) exposing the falx and the corpus callosum. Then callosotomy is performed and the frontal and parieto-occipital lobes are disconnected from the basal ganglia block.

The trans-Sylvian keyhole technique (Schramm et al., 2001) is done via a 4–5 × 4–6 cm craniotomy placed above the Sylvian fissure, followed by exposure of the circular sulcus which is limiting the insular cortex. Next step is complete opening of the ventricle from the temporal horn all around the basal ganglia block to the tip of the frontal horn via a transcortical disconnection. The next step is a temporomesial disconnection along the choroidal fissure carried forward beyond the choroidal point to the mesial arachnoid of the uncus. To gain histology it may be appropriate to remove parts of the HC-PHG block. The next step using the transventricular approach is the mesial disconnection of the frontal and parieto-occipital lobe, including a callosotomy from within the ventricle. To start the fronto-basal disconnection a mental line is drawn from the ascending M1 to the tip of the open frontal horn, the lateral surface of the basal frontal lobe is coagulated and with the aid of the microscope the disconnection is carried through the frontal white matter with a CUSA always following the outline of M1 and later A1. This leads automatically to the interhemispheric fissure where the disconnection line is then orienting itself along the outline of the A2 which leads around the anterior part of the corpus callosum to the roof of the corpus callosum. One can then follow the pericallosal artery always transecting the callosal white matter and one will automatically end-up at the inferior rim of the falx which then turns basally into the falcotentorial margin. Thus, in the posterior half of the mesial disconnection it follows the margin of the falcotentorial rim. This will lead the surgeon through the trigone down to the temporal area meeting the initial temporo-mesial disconnection. At the end of the mesial disconnection the isolated basal ganglia block has circumferentially been disconnected. It is advisable to then remove the cortex of the insula with suction underneath the M2 branches to remove a potential source of persisting seizures. Haemostasis is usually achieved only with oxidized cellulose followed by copious irrigation. Minor branches of the M3-M4 calibre can be sacrificed but all major M2 and M3 branches are preserved, as well as the posterior cerebral artery.

Perisylvian window techniques (Villemure and Mascott, 1995; Shimizu and Maehara, 2000) follow the same principle after exposure of the insular cortex by resection of the opercula.

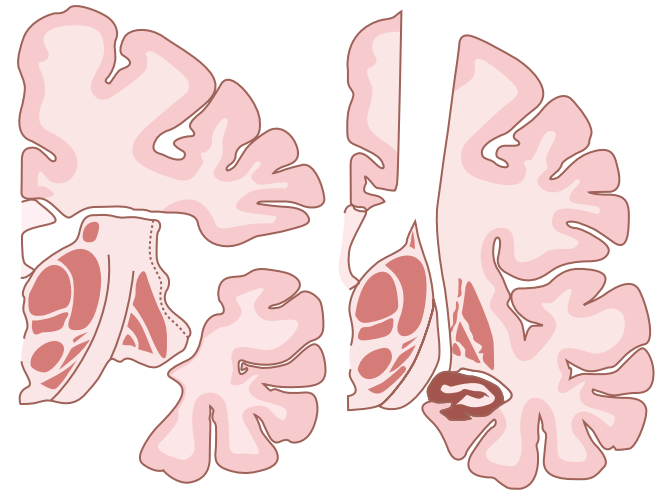

Fig. 83.8 Scheme of disconnections in trans-Sylvian keyhole (left) and dorsal transcortical hemispherotomy (right).
Courtesy of J. Schramm.

In dorsal transcortical transventricular hemispherotomy (Delalande et al., 2007), parasagittal craniotomy about 4 × 5 cm reaching about 3 cm behind the coronal suture is used. The lateral ventricle is accessed transcortically exposing the foramen of Monro and the posterior thalamus. A paramedian callosotomy is performed through this approach. A lateral disconnection is performed between the lateral border of the thalamus and the striatum from the ventricle reaching the temporal horn in the depth. Starting from the frontobasal part of the anterior callosotomy the posterior part of the gyrus rectus is removed and the transection line is extended laterally through the head of the caput caudatum and will then meet the lateral substriatal transection. Dorsally the substriatal disconnection line is connected to the posterior callosotomy line with suction, thus isolating the basal ganglia block from the hemisphere.

Both the trans-Sylvian and the dorsal transcortical hemispherotomies, have the advantage of low blood loss and small exposure with low transfusion rates. The dorsal approach preserves all of the superficial large vessels and avoids manipulation of the middle cerebral artery. The trans-Sylvian keyhole technique is ideal for patients with porencephaly or marked atrophy, suitable for near normal brain size, but for cases with hemimegalencephaly it is recommended to combine it not with opening the Sylvian fissure but with creating an opercular window similar to the perisylvian window technique.

Hemispherotomies are associated with unavoidable side effects such as completion of partial hemianopia, loss of fine pincer movement in the affected hand, sometimes deterioration in walking ability. Risks include all classical risks of craniotomy, development of hydrocephalus requiring a shunt, need for transfusions, and very rarely death. In modern series mortality rates around 1% have been described. There is also a certain risk of incomplete disconnection and of persisting seizures. All procedures are associated with a certain hydrocephalus rate varying between 5 and 30%, see discussion in (Schramm et al., 2012). Shunt rates in other series were 8%, 16%, 19%, and 23% for the modern hemispherotomies, for corticectomies up to 32% and in a large multicentre study of posthemispherectomy hydrocephalus with 690 patients the average rate was 23%. Anatomic hemispherectomy was a significant risk factor for developing hydrocephalus (Lew et al., 2013). Incomplete disconnection rates occur with every technique, even with Rasmussen's technique and incomplete resection rates between 2% and 30% have been described. Shunt rates are influenced by aetiology and surgery type. Particularly high shunt rates are observed in hemimegalencephaly patients. Shunt implantations may be necessary very late, 6–8 years after initial surgery. A recent survey of paediatric hemispherotomies described a mortality rate of 0.7% in 153 cases (Koubeissi et al., 2009).

Other operations for epilepsy

Callosotomy is a well-established procedure indicated for drop attacks, generalized tonic-clonic seizures (GTCS), atonic seizures, or Lennaux–Gastaut syndrome. By interrupting the propagation of ictal activity from one hemisphere to the other it is particularly useful to alleviate drop attacks and/or GTCS. It is frequently done limited to the anterior two-thirds or four-fifth of the corpus callosum, less frequently as a two-stage complete callosotomy (Spencer et al., 1988). Specific indications (partial vs. complete callosotomy) are less well defined than for other epilepsy resections. Among the many open questions, two are whether the anterior commissure should be transected, or whether the dorsal hippocampal commissure should be transected. Candidates for callosotomy frequently have several seizure types but the main aim is the abolition of drop attacks. It should be noted, that in about 25% of cases a temporary increase in focal seizures is observed.

In a series of 95 cases satisfactory seizure outcome (i.e. a combination of no seizures and over 75% reduction in seizure frequency was achieved in 77% of both, cases with leading drop attacks and with leading generalized tonic-chronic seizures. Anterior half callosotomy was found less effective than anterior two-thirds callosotomy (Tanriverdi et al., 2009). In the supine position an anterior unilateral frontal craniotomy, its medial border on the midline, about 6–7 cm long, 4 cm wide, allows to navigate around larger bridging veins. It is possible to sacrifice one smaller bridging vein. The non-dominant hemisphere is chosen for the interhemispheric approach. Arachnoid adhesions are carefully dissected under the microscope, especially where both hemispheres are adherent. Injury to the gyrus cinguli must be avoided, or at least restricted to one side. The corpus callosum is easy to identify, also helped by the two pericallosal arteries. These are carefully separated and covered by cottonoids. The transection of the corpus callosum can easily be done with bipolar and sucker or by CUSA at a very low setting. Some authors recommend to preserve the ependyma, but this is frequently impossible. In the supine position it is possible to reach far backward with the transection through a single frontal approach, but in case complete callosotomy is planned, some authors recommend separate frontal and parietal craniotomies. To determine the precise extent of transection one can either use a small strip of millimetre paper or intraoperative navigation. Some authors prefer the lateral decubitus position to allow the hemisphere to fall back, avoiding retractor pressure. In the lateral position it is more difficult to do a complete callosotomy through one craniotomy.

Disconnection or resection of hypothalamic hamartoma

These hamartomas may be pedunculated or broad-based and belong to the minority of lesions where seizures are generated inside the lesion. Removal is always difficult, a bit easier when using a transventricular endoscopic approach. Broad-based lesions are preferred for endoscopic disconnection. Side effects include memory deficits and considerable endocrine dysfunction (polyphagia, obesity). Alternative techniques include radiosurgery or electrocoagulation via a stereotactic electrode. Results are mixed, usually the rate of seizure freedom is well below 50%.

Multiple subpial transections (MST). MST belongs to the palliative procedures and is rarely used as a stand-alone intervention. It is mostly used as an add-on to lesionectomy or corticectomy when these areas border on motor, language, or visual cortex. To assess the effectivity of the procedure is difficult since no larger series of pure MST cases have been published (Schramm et al., 2002). Engel class I outcomes are rare, however, improvement, classified as Engel class II and III can be achieved in 45–70% of cases, somewhat depending on the definition of success for such a palliative intervention (Spencer et al., 2002). Opinions on the usefulness of MST are divided, arguments for and against have been summarized (Ojemann, 2006; Wyler, 2006). MST are based on the principle that the synchrony between groups of cortical neurons via bilateral spread within the ictogenic cortex could be weakened by interrupting the short lateral connecting fibres within the cortical layer, sparing the

efferent long fibres. Parallel cuts at 5 mm intervals are made with a blunt hook to a depth of about 5–6 mm across the superficial surface of a gyrus after inserting it into a tiny pial hole. Doing the same to the lateral banks of a gyrus is more difficult and more risky. Using the hook with the tip pointing downward appears to be a safer technique. Small bleedings are usually treated with oxidized cellulose and tamponade, larger bleedings are rare. Done in the motor cortex major deficits are exceedingly rare, some clumsiness is usually transient. Larger cortical areas may be treated in this fashion.

Deep brain stimulation is an augmentative and palliative technique. The indication is medically refractory partial seizures, including secondarily generalized seizures. In a prospective randomized study (Fisher et al., 2010) it was found that 54% of patients had a seizure reduction of at least 50% and 14 patients were seizure-free for at least 6 months. In the stimulated group 14% of participants reported depression and 13% memory problems. The procedure is not paid for in many countries, but mentioned here as an example of an augmentative modality fulfilling the criteria for successful palliative treatment. A recent review compares outcomes of different palliative procedures, including VNS versus callosotomy and MST (Fauser and Zentner, 2012).

Responsive cortical stimulator implantation

A recent randomized double-blind study (191 patients) for intractable partial epilepsy (Morrell, 2011) found after 12 weeks seizure frequency significantly reduced by 37.9% versus 19.3% in controls. Median seizure reduction increased to 44% at one year and to 53% at two years, and it ranged from 48% to 66% over postimplant years three to six (Bergey et al., 2015). Different healthcare systems will make different decisions regarding payment for implantation of these expensive palliative devices.

Box 83.1 Seizure outcome classifications

Engel outcome classification (Engel and Pedley, 2008)

- Class 1—free of disabling seizures
  - (completely seizure-free; non-disabling, simple partial seizures only; some disabling seizures, but free of disabling seizures for at least 2 years; generalized convulsion with antiepileptic drug withdrawal only)
- Class II—rare disabling seizures
  - (initially free of disabling seizures, but rare seizures now; rare disabling seizures since surgery; more than rare disabling seizures, but rare seizures for at least 2 years; nocturnal seizures only)
- Class III—worthwhile improvement
  - (worthwhile seizure reduction; prolonged seizure-free intervals amounting to more than half the follow-up period, but not less than 2 y)
- Class IV—no worthwhile improvement
  - (significant seizure reduction; no appreciable change; seizures worse)

ILAE outcome classification

1. Completely seizure-free; no auras
2. Only auras; no other seizures
3. 1 to 3 seizure days per year; ± auras
4. 4 seizure days per year to 50% reduction of baseline seizure days; ± auras
5. Less than 50% reduction of baseline seizure days; ± auras
6. More than 100% increase of baseline seizure days; ± auras

Postoperative

Outcome

Assessment of seizure outcome is not as simple as it appears. Ideally outcome should not only consider freedom from seizures but also quality of life. Ideal outcome is complete freedom of seizures including auras, including good quality of life, and full social re-integration. The most commonly used outcome scales mainly measure seizure outcome: Engel classification and the ILAE classification (see **Box 83.1**). Some seizures are severe, others hardly noticed in daily life, so seizure severity is very difficult to classify.

Minimum follow-up should be two years for outcome statistics. In general, TLE surgery outcomes are better than ETLE surgery outcomes (Engel class I between 65 and 75% for TLE, ETLE outcomes approximately 10% less), but a loss of about 1% seizure freedom per annum in the next couple of years is frequently observed. Reoperations carry success rates between 50 and 69% (Grote et al., 2016) A good discussion of outcome assessment problems and outcomes are described by Ojemann and Jung for TLE (Ojemann and Jung, 2006), and by Geller and Devinsky 2006 for ETLE (Geller and Devinsky, 2006) and Tellez-Zenteno and colleagues in 2005 (Tellez-Zenteno et al., 2005). Comparing operated with non-operated patients, Schmidt and Stavem (Schmidt and Stavem, 2009) concluded that 'the combination of surgery with medical treatment is four times as likely as medical treatment alone to achieve freedom from seizures'.

Complications

Epilepsy surgery, usually performed in younger and mostly healthy patients, carries the typical risks of cranial surgery (infection, haemorrhage, and so on), plus risks specifically associated with different epilepsy surgery types. See frequency and literature in Tanriverdi et al. (2009). Typical problems after TLE surgery include visual field defects, temporary dysphasia, and small infarcts and increased rates of depressive episodes. Cognitive side effects such as verbal memory decrease are observed after left-sided TLE surgery. Permanent morbidity rates around 2% are typically observed. Surgical complications (infection, thrombosis, and so on) are observed in 2–5% but rarely cause permanent sequelae. Mortality rates are well below 1%, in hemispherotomy series around 1%.

Controversy: Small or larger resection for TLE

This discussion is relevant only for mesial TLE. The hope is that restricted mesial resections (SAH) are associated with less cognitive side effects but similar seizure outcomes.

Evidence has been accumulating that seizure outcomes for SAH and TLR are rather similar (Schramm, 2008). In this review

most authors (6/8) found seizure outcome in SAH to be similar to that of lobectomy. There was evidence for a slightly better neuropsychological outcome for SAH in 11 of 14 studies. A meta-analysis (Josephson et al., 2013) based on 11 studies however found that 'participants were statistically more likely to achieve an Engel class I outcome after ATL compared with SAH'. The question whether a more limited mesial resection has comparable seizure outcome to TLR has not definitely been settled. The limitations of comparing studies using variable resection types have extensively been discussed (Schramm, 2008).

The question whether the mesial resection should be extended maximally in the dorsal direction is also open, since 7 of 12 studies (58%) in the first review found that seizure outcome was not related to extent of mesial resection. It is important to realize that there is only one prospective randomized study testing larger versus smaller mesial extent of resection (Schramm et al., 2011). The intent-to-treat analysis in this study with MRI volumetric determination of resection extent did not show a different seizure freedom rate for the more posteriorly reaching 3.5 cm resection group. This result remained the same when looking at volumetrically determined true resection length as compared to intended length.

Developmental disorders of the brain

Colin Ferrie, Daniel Warren, and Atul Tyagi

Introduction

Prenatal and postnatal development of the brain is controlled by a multiplicity of genetic mechanisms. Genetic abnormalities and environmental insults are responsible for a bewildering array of developmental disorders associated with brain malformations. Classic embryology remains key to understanding these, and an appreciation of the processes of gastrulation, dorsal and ventral induction, neuronal differentiation, proliferation, histogenesis, and migration and myelination will help the neurosurgeon understand the conditions likely to be encountered in clinical practice. In this chapter the more common and many less common brain malformations are reviewed. These include anencephaly, holoprosencephaly, septo-optic dysplasia, schizencephaly, grey matter heterotopias, lissencephaly/pachygyria, polymicrogyria, porencephaly, developmental anomalies of the corpus callosum, microcephaly, hemimegalencephaly, posterior fossa malformations, and encephaloceles. The emphasis is on promoting an understanding of concepts and on clinical implications, rather than on imparting detail.

Brain development: An overview

Classic neuroembryology remains key to understanding brain development and the processes which may go wrong with it (Sarnat and Flores-Sarnat, 2013). Brain development is conventionally divided into stages, during which pathological processes (genetic and non-genetic) give rise to distinct malformations. However, it is a simplification to assume these necessarily represent discrete, time limited processes, and that one ends before the next begins.

Gastrulation

Around the third week of embryonic development so-called gastrulation occurs (Figs. 84.1 and 84.2), resulting in the formation of a three-layered structure comprising exo, meso, and endoderm. Problems during this phase gives rise to a multiplicity of conditions affecting non-nervous system (CNS) and CNS structures, including spinal cord anomalies, neurenteric, dermoid and epidermoid cysts, and anterior meningoceles

Dorsal induction

This occurs at about 3–4 weeks' gestation, with the key outcome being the formation of the neural tube. Mesoderm cells migrate rostrally towards the primitive node (formed during gastrulation), forming the notochord, and also inducing ectoderm to form neuroectoderm comprising the neural plate. This then differentiates into two layers which ultimately form the neural tube and the neural crests. Formation of the neural tube is called neurulation, and involves the neural plate rolling up and fusing. Neurulation (Fig. 84.3) is divided into primary and secondary neurulation which are key stages in the formation of the neural tube from the rostral end of the notochord to its caudal end at the L1–L2 level and the formation of the lower lumbar, sacral, and coccygeal vertebral segments, respectively.

Dorsal migration of neural crest cells is responsible for the formation of many cell populations and structures, including melanocytes, craniofacial cartilage and bone, smooth muscle, peripheral and enteric neurons, and glial cells.

Ventral induction

Ventral induction occurs between the fifth and tenth week of gestation and comprises two key processes: the formation of several vesicles, which will give rise to the brain, from the rostral end of the neural tube; and flexures which will divide the brain into different parts.

Initially three vesicles form during neuropore closure: the prosencephalon; mesencephalon; and rhombencephalon, which give rise to the fore, mid, and hind brain, respectively. Further differentiation of the prosencephalon gives rise to the telencephalon (rostrally) and diencephalon (caudally) and of the rhombencephalon to the metencephalon and myelencephalon. The cephalic flexure separates the fore from the midbrain and the cervical flexure separates the hindbrain from the spinal cord.

Diverticula of the telencephalon (the telencephalic vesicles) give rise to the cerebral hemispheres with the central cavities giving rise to the lateral ventricles. The diencephalon develops into the thalamus, hypothalamus, epithalamus, optic cups, and neurohypophysis, with the associated central cavity forming the third ventricle. Lateral out-pouchings of the telencephalon form the retinae and optic nerves. Rapid growth of the telencephalon, particularly

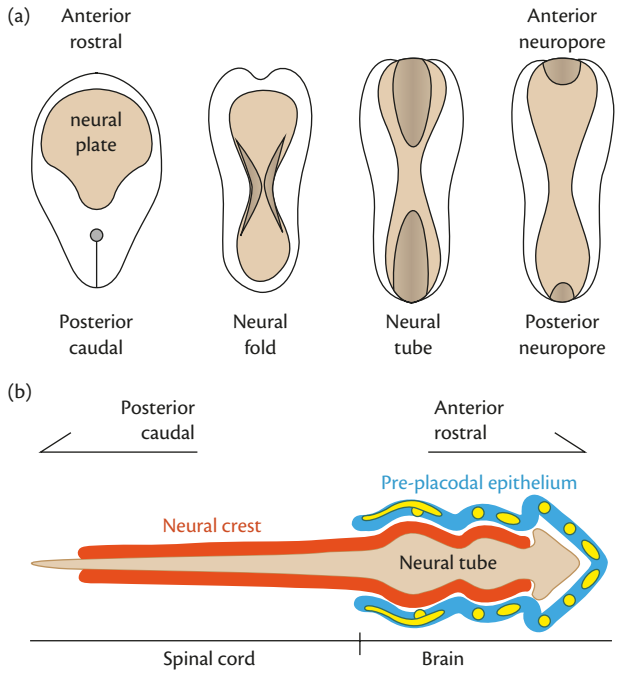

Fig. 84.1 (A) During the third week of gestation, the dorsal ectoderm forms the neural plate anterior to the node (dark circle). By the end of the third week, the neural plate has invaginated to make a neural fold, which then closes up to form a neural tube. Neural tube closure proceeds both rostrally and caudally from a starting point near the location of the future neck. Two openings, the anterior and posterior neuropores, are the last areas of the neural tube to close. (B) This cartoon shows a dorsal view of the three-vesicle embryo with rostral to the right and caudal to the left. Immediately surrounding the neural tube is neural crest, which gives rise to most of the peripheral nervous system. Within the primordial head region of the developing embryo, neuroepithelium develops into preplacodal ectoderm (blue area), which eventually populates seven bilateral pairs of placodes (yellow areas), five of which give rise to sensory neurons.

the outer regions, cause it to cover the diencephalon, midbrain and hindbrain and ultimately gives rise to the characteristic 'C' shape of the lateral ventricles. Trapped mesenchyme between the developing cerebral hemispheres gives rise to the falx.

Development of the mesencephalon is much less dramatic than that of the prosencephalon. The mesencephalic flexure separates it from the rhombencephalon. The shrunken central cavity gives rise to the aqueduct. Cells on the dorsal side of the neural tube (the alar plate) migrate dorsally, giving rise to the tectal plate, including the superior and inferior colliculi. Others migrate ventrally to form the red nuclei and substantia nigra.

Later the pontine flexure develops separating the rhombencephalon into two parts. The myelencephalon forms the medulla oblongata and the metencephalon forms the pons and the cerebellum (with a contribution from the mesencephalon). Splaying of the rhombencephalon and stretching of the roof plate leads to the formation of the fourth ventricle.

Neural proliferation, differentiation, and histogenesis

Initially a single layer of neuroepithelial cells lines the neural tube, bounded by the internal and external limiting membranes. Proliferation of neuroepithelial cells gives rise to a pseudostratified epithelium and the outermost cells move towards the centre of the cavity of the neural tube. The innermost layer (the ventricular zone) borders the cavity and is the site of mitotic division. The future neurones (neuroblasts) subsequently migrate outwards to form the mantle zone which later becomes the grey matter. External to this is an acellular layer, known as the marginal zone. This becomes the white matter. Neurones in the mantle zone send axons into the marginal zone and outwards beyond the neural tube as motor fibres. Astrocytes and oligodendrocytes are also formed from neuroepithelial cells (glioblasts) dividing by mitosis in the ventricular zone and lastly ependymal cells are formed, covering

the developing ventricular system. Microglia are derived from mesenchyme.

In the fourth week of embryonic life, proliferating neuroblasts in the mantle zone give rise to ventral and dorsal thickenings on either side of the neural tube (the basal and alar plates, respectively), separated by the sulcus limitans. The basal plate later gives rise to motor neurones and the alar plate to sensory neurones. In the brain stem the sulcus limitans separates the motor and sensory cranial nerve nuclei. Subsequent migration in various directions gives rise to the final position of the various brain stem nuclei. The margins of the alar plates (the rhombic lip) give rise to the cerebellum.

The mantle zone of the developing telencephalic vesicle is responsible for the grey matter of the cerebral hemisphere, the basal ganglia, and the hippocampi. The corpus striatum begins as a thickening of the mantle zone of the basal part of the telencephalic vesicle. It is later divided into medial and lateral parts by descending axons constituting the internal capsule. The remainder of the mantle zone of the telencephalic vesicle is thinner and is called the pallium. This becomes the cerebral cortex. In the medial wall of the pallium a thickening arises and bulges into the developing lateral ventricle. This gives rise to the hippocampus; the hippocampal sulcus separating it from the rest of the pallium

Neuronal migration

Nearly all neurones of the brain mature at sites distant form their origin. They do so as neuroblasts (rather than as neurones) but the process is conventionally known as neuronal migration (Fig. 84.4). Most neurones reach what will be the cerebral cortex (the cortical plate) by migrating along radial glial cells from the subventricular zone towards the pial surface. The cells migrating earliest become the deepest layer of the cortex, hence later migrating cells travel through earlier migrating cells. Eventually the mature six-layered cortex is formed. A minority of neurones migrate tangentially from the ganglionic eminence of the germinal matrix along axons rather than radial glial cells. These are destined to become GABAergic interneurons. Similar migratory processes are involved in the development of the cerebellar cortex and certain brain stem nuclei.

Axon sprouting begins during neuronal migration. It involves formation of short and long axons for nearby and distal targets, respectively. The dendritic tree mostly forms after migration has ceased, and is followed by synaptogenesis. Many more neurones are formed than ultimately comprise the mature brain; apoptosis is an important aspect of brain development. It generally coincides with synaptogenesis.

Myelination

Myelination begins (in the spinal nerve roots, some cranial nerves, and some longitudinal tracts of the brainstem) at 24 weeks' gestation and is mostly completed by two years of age. However, it is not until the fourth decade that the ipsilateral frontotemporal association bundle is fully myelinated.

Control of brain development

Brain development is under precise genetic control. A multiplicity of genes regulates development (Hu et al., 2014). These interact together, many only being expressed during limited periods. Some appear to only control development within the CNS, others also have roles outside the CNS. Some have different functions during different periods of development. Environmental factors are also important (Gressens et al., 2001). For example, retinoic acid (vitamin A) is important in controlling the expression of Hox genes, important in the regional control of brain development.

Many different mechanisms have been identified as important in the control of brain development (Sarnat and Flores-Sarnat, 2014). Induction refers to the influence one embryonic tissue has on another. Hence neural induction denotes the influence of non-neural tissue (e.g. the notochord) on the neural tube. Recognition molecules, adhesion molecules, cytoskeletal components, and physical barriers (such as the dorsal and ventral median septa) all play a role on the regulation of neuronal migration.

Abnormal brain development (brain malformations)

Classifications

There are numerous malformations of the brain, some relatively common others extremely rare. Bringing order involves classification. Traditionally this has been based on morphology, previously determined by pathological examination, but more recently by neuroimaging. An alternative approach has concentrated on when during developmental life various malformations have been thought to arise. Most recently classification based upon aetiology has been proposed. None of these is entirely successful. Pure morphological classification fails to take account of the explosion in our knowledge of genetics. However, non-genetic aetiologies are also important.

Combined approaches are popular (de Wit et al., 2008).

Description of selected malformations.

Anencephaly

Anencephaly, along with encephaloceles and the spina bifidas, are generally classified together as neural tube defects, as they are disorders of neurulation. In anencephaly, there is failure of the rostral neuropore to close at 24 days, resulting is an open defect (often very large), involving the skin and calvaria; a degenerate and haemorrhagic brain mass lies on the exposed basicranium. Anencephaly may occur with other neural tube defects, and also with a wide variety of extra-CNS problems. Attempts should be made to define these in case they have genetic implications.

Anencephalic foetuses often spontaneously abort. The condition is uniformly fatal in those born alive, often within minutes of birth, although survival for hours, and occasionally up to a few weeks is well recognized.

The cause of anencephaly remains poorly understood, although interplay of genetic and many environmental factors is clear. Familial recurrence is relatively common and there are associations with both young and old maternal age. There are striking geographical and secular variations in its incidence. Nutritional deficiencies, particularly of folate, appear to be important.

Anencephaly can be readily diagnosed antenatally, and therapeutic termination considered.

Holoprosencephaly

Holoprosencephaly (Fig. 84.5) is a heterogeneous group of disorders whose origins relate to pathogenic processes operating during the first four weeks of gestation. It principally affects the forebrain and face but there is also variable involvement of posterior fossa structures. Its aetiology is diverse, involving genetic and acquired mechanisms. This is reflected in it occurring as both an isolated malformation and in syndromic forms. Established teratogenic causes include maternal diabetes, retinoic acid, and alcohol. Karyotype abnormalities, especially trisomy 13 and 18, are common, and mutations of at least nine different genes affecting both dorsal and ventral patterning have been implicated (including the prosaically named sonic hedgehog gene). Recognized mutations appear to be responsible for only a tiny fraction of sporadic cases of holoprosencephaly.

Traditionally holoprosencephaly is classified as alobar, semilobar, and lobar. Alternatively, it can be divided into complete and incomplete forms. All result from failure of cleavage in the anatomic planes. In alobar holoprosencephaly there is no separation of the cerebral hemispheres, which are represented as a unified holosphere and monoventricle. In lobar holoprosencephaly there is complete separation of the hemispheres but with absent or hypoplastic olfactory bulbs and tracts (arrhinencephaly). The deep grey matter is fused to a variable extent.

Semilobar holoprosencephaly presents with intermediate changes, usually with small variably fused frontal lobes, separated occipital lobes, and a falx present posteriorly. A relatively recently identified form is characterized by separation of the frontal and occipital lobes and deep grey nuclei but fusion of the posterior frontal and parietal convexities and absence of the body (but not genu or splenium) of the corpus callosum.

Holoprosencephaly can be associated with many other brain malformations, including: agenesis of the corpus callosum (with

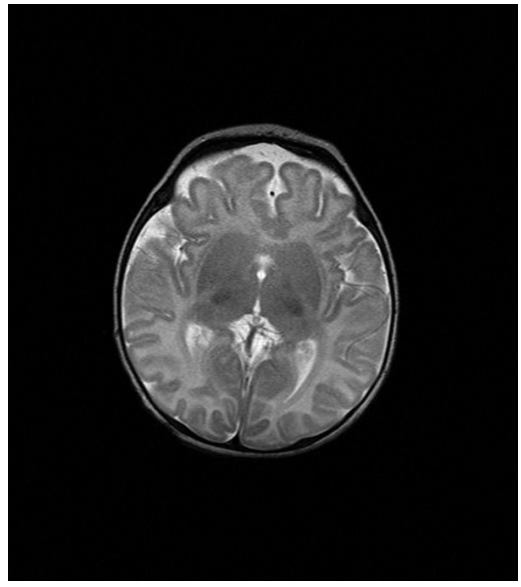

Fig. 84.5 Axial T2 of a 3 week of child with semilobar holoprosencephaly presenting with diabetes insipidus. Imaging demonstrates isolated partial frontal lobe fusion.

no Probst's bundles), fused and /or hypoplastic brain stem nuclei; abnormalities of the cerebellar hemispheres and/or vermis; Chiari 1 malformation; rhombencephalosynapsis; dorsal cysts; and hydrocephalus. Dorsal cysts are often large and lie posteriorly in the sagittal fissure or, in alobar holoprosencephaly, behind the holosphere. They sometimes represent an expansion of a single lateral ventricle, or else an extreme dilation of the third ventricle.

Hydrocephalus is often associated with the presence of a dorsal cyst, or may be a consequence of extruded germinal matrix in the ventricles. Abnormalities of neuronal migration, cortical organization, and myelination are common in holoprosencephaly. In part, these are responsible for associated developmental problems, such as learning difficulties and epilepsy.

It is said that in holoprosencephaly the face mirrors the brain, in that the more severe the facial abnormality generally the more severe the brain malformation; but there are many exceptions. The face may be normal or at the most extreme, there may be cyclopia with a single midline orbit with absent ocular structures, arrhinia (or a supraorbital proboscis), a hypoplastic or absent mandible, and otocephaly. Less severe facial abnormalities include, hypotelorism (rarely hypertelorism), nasal abnormalities, such as choanal atresia and single nostril, cleft palate or lip, and small mouth.

A majority of those with holoprosencephaly die within the first few months of age, but an increasing minority survive into early childhood and beyond. Death results from both the effects of the CNS malformation, and from associated non-CNS problems. Milder cases have a near normal life expectancy.

Most babies with holoprosencephaly are hypotonic and may remain so, but spasticity often develops. Learning difficulties are expected and, in alobar cases, are usually severe-profound. The mildest cases may have normal or near normal intelligence. Epilepsy, although not constant, is very common and is often severe and intractable.

Early, detailed MRI imaging to fully define the malformation is important. There may be difficulties distinguishing some cases from hydranencephaly and severe hydrocephalus. Vascular imaging to determine the position and configuration of the anterior cerebral arteries and dural sinuses can be helpful. Unless a teratogen is clearly implicated as the cause, a clinical genetic assessment is essential to determine if the malformation is isolated or syndromic. Endocrine and cardiac assessment is also important. Neurosurgical involvement will be required in cases with associated dorsal cysts and/or hydrocephalus.

Septo-optic dysplasia (also known as septo-optic-pituitary dysplasia complex)

This disorder is among the best known of the cerebral malformations (Fig. 84.6). Its three cardinal features—absence of the septum pellucidum, optic nerve hypoplasia, and pituitary dysfunction—can occur as isolated findings, or in any combination. There may be other associated brain malformations, which give important clues regarding likely aetiology.

Isolated absence of the septum pellucidum is not associated with detectable neurodevelopmental problem in humans, although it can lead to navigational problems in rats. Cases of partial absence of the septum are described. Anterior displacement of the fornices and septal veins may give a false impression of partial presence of the septum. In addition, cases of a wide cavum septum pellucidum are reported in association with optic nerve hypoplasia and/or pituitary problems. Optic nerve hypoplasia can be unilateral or bilateral (in which case it can be symmetrical or asymmetrical). It can be associated with anything form near normal vision to blindness. Visual field defects and restriction of peripheral vision can also occur. There may be associated optic atrophy as well as hypoplasia. Hypopituitarism can present in the neonatal period with hypoglycaemia. However, the most common presentation is with growth failure due to growth

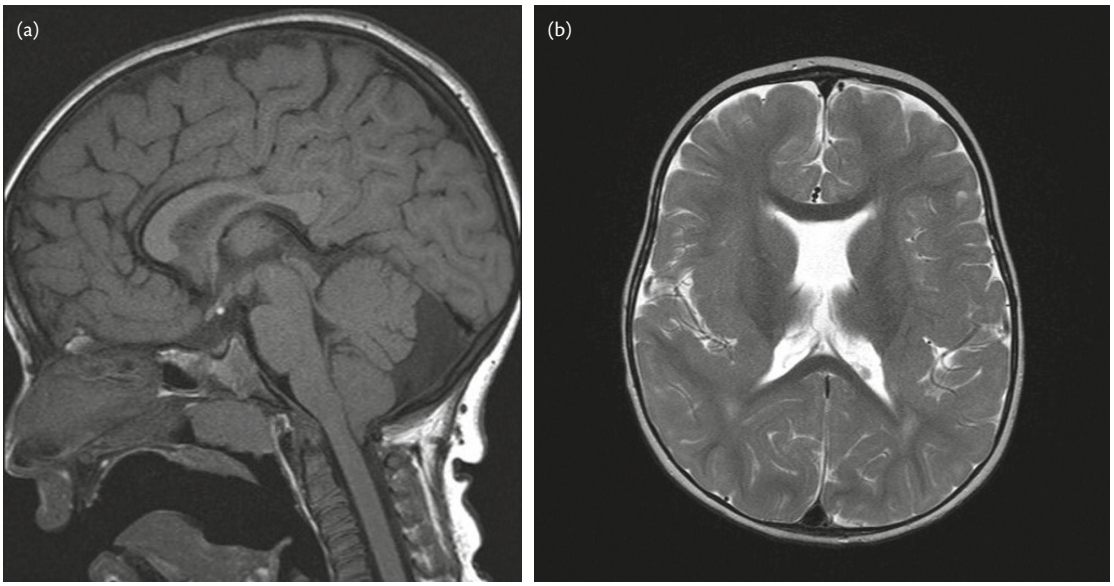

Fig. 84.6 Septo-optic dysplasia. Sagittal T1 (Fig. 84.6A) demonstrates an ectopic posterior pituitary 'bright spot' posterior to the optic chiasm, in addition to an incidental Chiari I malformation. Axial T2 (Fig. 84.6B) confirms absence of the septum pellucidum and concomitant abnormal thickening of the posterior perisylvian cortex consistent with associated perisylvian polymicrogyria.

hormone deficiency. Other pituitary hormones can be affected, and a minority of patients develop pan hypopituitarism.

The most common associated brain malformations are agenesis of the corpus callosum, lobar holoprosencephaly, schizencephaly, and focal cortical dysplasia. Hydrocephalus has been described.

The core features of septo-optic dysplasia suggest an insult during ventral induction. Young maternal age and primiparity are significant risk factors. Most cases are probably non-genetic in origin, although mutations in a multiplicity of genes are described as giving rise to various features of the condition. Various teratogens, including medicinal and non-medicinal drugs and congenital viral infections, are also implicated. A vascular pathogenesis seems probable in many cases and some of the CNS abnormalities associated with the condition may be explained by further vascular insults later in gestation.

Absence of the septum can be detected antenatally and gestational age-specific measurements of the optic nerve diameters are available. However, the condition may only be diagnosed after the possibility of therapeutic abortion is past.

Schizencephaly

This malformation is characterized by a unilateral or bilateral cleft(s) running from the ventricular margin to the pial surface (Fig. 84.7). The clefts are lined with heterotopic grey matter, usually polymicrogyria. This separates the condition from porencephaly. The sides of the cleft may be separated or apposed (open and closed lip schizencephaly). They are usually located in the region of the sylvian fissure, but may be more anteriorly or posteriorly located. Schizencephaly may be isolated or else associated with other brain malformations, including: polymicrogyria, elsewhere in the cerebrum; agenesis of the corpus callosum; absent septum pellucidum; and septo-optic dysplasia. There may also be hydrocephalus.

The clinical manifestations are very variable, and reflect the position and severity of the cleft or clefts and any associated malformations. Motor deficits (hemi or tetraplegias), learning difficulties (mild to severe) and epilepsy are common. Epileptic seizures are most often focal, but can be generalized, and are often drug-resistant.

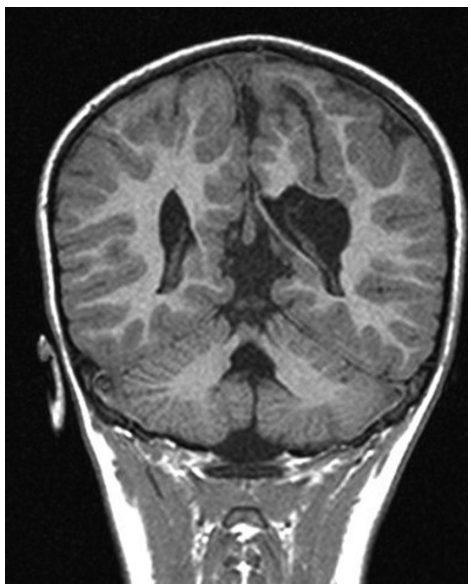

Fig. 84.7 Coronal T1 demonstrates a left hemispheric closed lip schizencephaly—note the vertical cleft extending from the lateral ventricular margin to the pial surface with the walls in near apposition and lined by abnormally thickened cortex (polymicrogyria). The midline corpus callosum is additionally absent.

Schizencephaly is a malformation arising during neuronal migration and cortical organization. A vascular aetiology is widely postulated. Familial cases are recognized and some genetic mutations are known to give rise to it. However, most cases are sporadic and drug and infective teratogens are also important in terms of aetiology. The more severe cases can be detected antenatally.

Grey matter heterotopias

Grey matter heterotopias are characterized by the presence of neurones outside the cortex (Fig. 84.8). Two main types are described: nodular, and laminar (band).

Nodular heterotopias are made up of rounded masses of normal neurones and glial cells, without laminar organization, in various positions between the ependymal lining of the ventricles and the normal cortex. They have the signal characteristics of normal grey matter, which helps distinguish them from the subependymal nodules of tuberous sclerosis. Most commonly they lie adjacent to the ependymal lining and are termed periventricular nodular heterotopias. They can be single or multiple, unilateral, or bilateral, symmetrical, or asymmetrical. Nodular heterotopias may be asymptomatic, but they frequently give rise to epileptic seizures, which may be focal or generalized. The latter suggests functional connectivity to thalamocortical circuits. Many individuals with nodular heterotopias function within the normal range intellectually and without physical difficulties. However, others, particularly those presenting in childhood, have learning and motor difficulties of variable severity. Nodular heterotopias can obstruct the aqueduct, causing hydrocephalus. Nodular heterotopias usually arise in isolation, but can be associated with other brain malformations, including Chiari II malformations.

Nodular heterotopias can be associated with cardiac, connective tissue and blood clotting abnormalities. This appears to be largely a consequence of mutations in filamin 1 (also called filamin A); screening is recommended.

Bilateral periventricular nodular heterotopia is much more common in females. This is a consequence of most cases being caused by filamin 1 mutations, which is X-linked dominant, and usually lethal in males. Non-genetic factors are thought to be responsible for most unilateral cases. They frequently occur in the posterior peritrigonal regions, which are vascular watersheds. Associated hippocampal abnormalities are frequent. Periventricular nodular heterotopias can be detected antenatally.

Band heterotopia is characterized by two layers of cortex in the cerebral hemispheres (hence, double cortex syndrome). The heterotopic layer lies in the white matter beneath the true neocortex and is unlayered. It is of variable thickness and follows the normal cortex, but is lacking in the cingulate and temporal cortex. Cases with two abnormal bands are described. The overlying cortex usually appears normal or may be thickened. Other abnormalities may include ventriculomegaly, thinning of the corpus callosum, and cerebellar vermian abnormalities. The thickness of the abnormal band correlates with the severity of the associated developmental problems. Epilepsy is expected. It usually begins in early–mid childhood, but onset can be earlier or later. Intellect varies from low

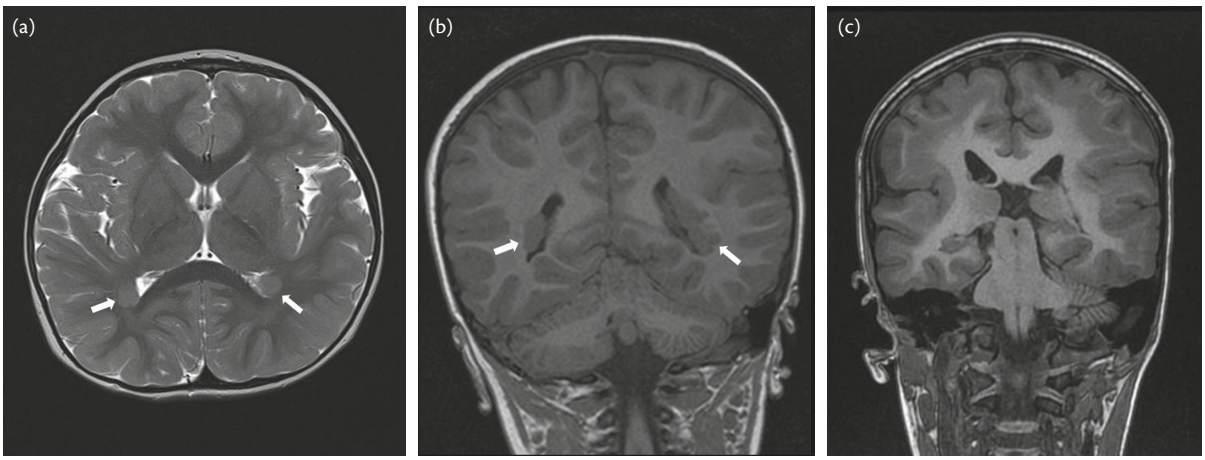

Fig. 84.8 Axial T2 (Fig. 84.8A) and coronal T1 (Fig. 84.8B) demonstrate bilateral periventricular grey matter heterotopia (white arrows) in a 4-year-old female with a complex seizure disorder; the heterotopia is iso-intense to the brain parenchyma grey matter on both T1 and T2 sequences. Figure 84.8C (coronal T1) demonstrates bilateral band heterotopia ('double cortex syndrome').

normal to severe learning difficulties. There may be motor problems as well.

Band heterotopia is a genetic disorder of neuronal migration. It is predominantly X-linked dominant, occurring in females but with lethality in males and is due to mutations of the doublecortin (*DCX*) gene. Some *DCZ* mutations are non-lethal in males, but give rise to lissencephaly, a more severe neuronal migration disorder. A small number of males are described with band heterotopia, caused by somatic *DCX* mutations.

Lissencephaly (smooth brain) and pachygyria

Classic Lissencephaly (also called type 1 lissencephaly)

Classic lissencephaly (usually shortened to just lissencephaly), is a brain malformation in which the cerebral cortex lacks (partially or completely) normal sulci (agyria) and is abnormally thick (pachygyria) (Fig. 84.9). At its most extreme, the brain presents as a figure of eight similar to that expected towards the late second trimester. The thickened cortex classically consists of only four layers. Affected individuals are often diagnosed soon after birth as a consequence of severe hypotonia and feeding difficulties. Severe-profound learning difficulties and increasing spasticity are expected. Epilepsy is usually severe. Rarely there are other associated CNS and non-CNS manifestations, depending on the genetic cause. Life expectancy is greatly reduced, with the most severely affected subjects often dying in infancy.

Lissencephaly is a genetic disorder of neuronal migration. Most cases are due to mutations on the *Lis1* gene. This gives rise to the most severe phenotype with a characteristic posterior-anterior gradient in the severity of the malformation. Some patients have a visible deletion on the short arm of chromosome 17 and a characteristic dysmorphic facial appearance known as the Miller-Dieker syndrome. The second commonest cause is X-linked lissencephaly due to *DCX* mutations, with an anterior-posterior gradient. X-linked lissencephaly can also be due to *ARX* mutations in which there is often ambiguous genitalia. Lissencephaly can also occur as a manifestation of a tubulopathy, particularly with mutations of *TUBA1A*. In this it may be associated with dysgenesis or agenesis of the corpus callosum and cerebellar hypoplasia.

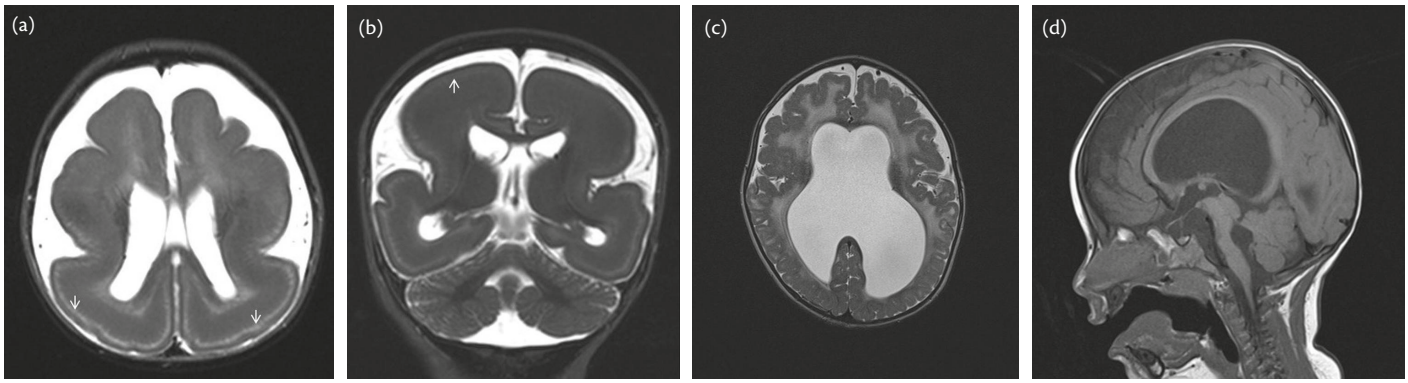

Fig. 84.9 Lissencephaly. (A, B) A 6-month-old child presenting with failure to thrive and generalized seizures. Axial T2 imaging in the axial (a) and coronal (b) plane demonstrate classic lissencephaly with a thin outer cortical layer and white matter cell sparse layer (white arrows) separated from deeper arrested neurons. Shallow sylvian fissures result in a 'figure of eight' configuration. (C and D) A 14-month-old child with confirmed Walker-Warburg syndrome. Axial T2 (C) demonstrates abnormally shallow bifrontal sulcation with delayed myelination and sagittal T1 (D) shows additional pontine hypoplasia.

An antenatal genetic diagnosis is often available in affected families. Neuroimaging can detect lissencephaly from the very late second trimester.

Cobblestone lissencephaly (also called type 2 lissencephaly)

Cobblestone lissencephaly occurs in three related disorders, all of which also feature congenital muscular dystrophy and developmental eye problems (which may be mild to severe): Walker-Warburg syndrome; Fukuyama syndrome; and muscle-eye-brain. They are alpha-dystroglycanopathies caused by deficient glycosylation of alpha-dystroglycan, due to mutations in a large number of different genes. In cobblestone lissencephaly, the surface of the brain is bumpy the glia limitans being broken, causing leptomeningeal, neuronal, and glial heterotopias. Cobblestone lissencephaly is nearly always part of a complex malformation, particularly also involving the cerebellum. Hydrocephalus is constant in Walker-Warburg syndrome, occasional in muscle-eye-brain disease, but is not a feature of Fukuyama syndrome.

Polymicrogyria

The hallmark of polymicrogyria is the presence of excessive, abnormally folded small fused gyri. On MRI its appearance is variable. Often it presents as multiple small gyri (which may be confused with the polygyria seen in some cases of hydrocephalus). Alternatively, it may appear as thickened cortex (making distinction from pachygyria difficult) with a 'bumpy' grey-white junction or as a smooth area of cortex (which if extensive may be confused with lissencephaly). The grey-white junction is often 'blurred' and the underlying white matter is often thinned. It can be unilateral or bilateral (in which case it can be symmetrical or asymmetrical), localized, or extensive. Certain distinct distributions, with aetiological implications, are recognized. These include bilateral frontal, bilateral fronto-parietal, bilateral perisylvian, bilateral parasagittal parieto-occipital, bilateral generalized, and unilateral perisylvian. There are frequently additional cerebral malformations reflecting the diverse aetiologies of polymicrogyria.

The clinical manifestations reflect a combination of the topographical distribution of the abnormal cortex, its extent, other associated malformations, and the underlying aetiology. Some cases are diagnosed shortly after birth as a consequence of severe motor problems (which may include arthrogryposis), feeding difficulties, and epilepsy. Others may only come to light as an incidental finding or following the diagnosis in a family member. Individuals with relatively subtle neurodevelopmental/neuropsychiatric disorders may be found to have polymicrogyria. Epilepsy with focal or generalized seizures is common and can present at any age. However, it is by no means constant and in contrast to when it complicates many other cerebral malformations, may be time limited, and/or responsive to antiepileptic drug medication. Because of its predilection for the peri-Sylvian regions, pseudobulbar problems are common in those with polymicrogyria.

Polymicrogyria is caused by diverse genetic and acquired insults to the developing brain. Histological features suggest many cases arise after neuronal migration is completed at around 20–24 weeks' gestation. However, other histological features suggest an earlier origin, at least in some cases, prior to the fourth month of gestation while neuronal migration is occurring. Vascular insults and *in-utero* infections (such as rubella, cytomegalovirus, and toxoplasma infection) are important acquired causes of polymicrogyria. Chromosomal abnormalities are common in polymicrogyria. Particularly important is deletions involving 22q11.2 in which perisylvian polymicrogyria is often accompanied by congenital heart defects and immune deficiency. Several specific genetic mutations have been found in familial cases of polymicrogyria, particularly but not exclusively when this is bilateral. Polymicrogyria is a feature of some metabolic disorders, including Zellweger syndrome (a peroxisomal disorder), organic acidurias, aminoacidaemias, and mitochondrial disorders. Consequently, a thorough diagnostic workup is essential.

Porencephaly

The terminology of porencephaly is confusing. A true porencephalic cyst is a focal cavity in the cerebral hemisphere which communicates with the ventricular system. It may appear to also communicate with the subarachnoid space over the cerebral convexity but nearly always there is a thin membrane separating the two. The cyst lacks internal structure and is lined with white matter. The terms congenital or clastic porencephaly are sometimes applied. Porencephaly is also sometimes applied to full thickness cysts lined with abnormal cortex (such as polymicrogyria). This can be called developmental porencephaly but the term schizencephaly is now generally preferred, as its aetiology is different (see earlier).

The clinical features of porencephaly reflect the size and position of the cyst and the underlying cause. Common problems include cerebral palsy (spastic in type, unilateral, or bilateral), learning difficulties, and epilepsy. Epilepsy occurs in around a third of affected patients and can begin from infancy to adult life. If the former it may present as an epileptic encephalopathy with apparent generalized seizure types. Later focal seizures are common. Startle-induced seizures are a well-recognized association. Rarely porencephalic cysts can expand and cause pressure effects, due to pulsation caused by the choroid plexus.

Porencephaly is generally caused by acquired insults to the brain acting from the late second trimester to the early postnatal period. Ischaemia and haemorrhage are numerically the most important aetiologies, but other causes include trauma and infection. Familial, autosomal dominant, cases can be caused by mutations in *COL4A1*, which codes for a very widely expressed collagen. Associated white matter abnormalities and calcification may help recognition. The *COL4A1* phenotype is extensive and genetic counselling essential. There is a risk of haemorrhagic stroke during childhood and adult life.

Agenesis of the corpus callosum, and other developmental anomalies of the corpus callosum

During embryogenesis, commissures connecting contralateral areas of the developing brain form. The most important of these is the lamina terminalis extending from the roof plate of the diencephalon to the optic chiasm. Others include the anterior and posterior commissures and the hippocampal commissure. Formation of the corpus callosum involves apoptosis of the lamina terminalis, allowing developing callosal fibres to project across the midline. Agenesis of the corpus callosum is caused by interference in this, with the lamina terminalis acting as a barrier rather than a facilitator. The obstructed fibres are deflected posteriorly along the medial wall of the developing hemisphere as bundles of Probst. The presence of these distinguish primary agenesis from later destructive abnormalities of the

corpus callosum. The corpus callosum forms rostral to caudal; in partial agenesis, the splenium is most likely to be absent, followed by the rostrum, with deficiency of the mid-portion the least common. Hypoplasia of the corpus callosum, in which all parts are present but abnormally thin, arises from a deficiency of nerve fibres, from whatever cause. Probst bundles are not present.

The neuroimaging features of complete agenesis of the corpus callosum include widely spaced lateral ventricles which lack the normal midline convexity, upward displacement of the third ventricle, Probst bundles lying between the bodies of the lateral ventricles above the third ventricle and often prominence of other commissures.

Agenesis of the corpus callosum can be isolated or associated with a wide variety of other developmental anomalies of the brain, particularly of midline structures. Facial dysmorphism, particularly hypertelorism, is common. Significant developmental problems are usual, including learning difficulties, ranging from mild to profound; motor problems; and epilepsy. These are often mainly a consequence of associated abnormalities. Isolated agenesis may appear asymptomatic, with other interhemispheric connections (normal and abnormal) taking over the function of the corpus callosum. However, detailed neuropsychological assessment will usually reveal visual processing, fine motor, and specific language difficulties.

Agenesis of the corpus callosum is often genetic in origin, occurring as a consequence of certain chromosomal abnormalities and single gene defects. Of particular interest are its frequent associations with X-linked hydrocephalus due to aqueduct stenosis, and agenesis of the corpus callosum with mental retardation and spasticity. Both are caused by mutations of *L1CAM*, which codes for a cell adhesion molecule. It can also arise as a consequence of various metabolic disorders and from the effects of teratogens, including alcohol.

Microcephaly and macrencephaly

Microcephaly is defined as a head circumference more than three standard deviations below the population mean. It is almost, but not quite synonymous with macrencephaly (small brain), since the brain may be small, but the head size normal. It is usual to classify it as congenital (or primary) or acquired (or secondary), depending on whether the head is a normal size at birth. The gyral pattern may be normal (microcephaly vera), simplified, thickened (microlissencephaly), or show polymicrogyria. The corpus callosum may be absent. Microscopic examination may reveal neuronal depletion, particularly in cortical layers II and III.

The causes of microcephaly are protean, encompassing most pathological processes affecting the brain. This is reflected in its diverse clinical manifestations, which range from normal to severe disability. Significant learning difficulties are the norm, but are by no means universal.

Any pathological process causing destruction of brain tissue, or interfering with brain growth, acting antenatally, or in infancy or early childhood, will result in microcephaly. Genetic microcephaly occurs with autosomal recessive, autosomal dominant, and X-linked inheritance patterns. The first of these is the most common. There are now at least six recognized genes, mutations in which give rise to autosomal recessive microcephaly. Many of the genes causing microcephaly have important roles in the regulation of neuronal proliferation and apoptosis. The study of genetic microcephaly is likely to be very helpful in aiding understanding of brain development in general (Gilmore and Walsh, 2013).

Hemimegalencephaly

This is a complex brain malformation characterized by an abnormally large cerebral hemisphere. Occasionally an abnormally small cerebral hemisphere (hemimicrencephaly) can give rise to diagnostic confusion. Although usually confined to the forebrain, the mid, and hind brains are sometime involved as well. Pathologically there is abnormal proliferation of both neurones and glial cells. The cortex tends to be abnormally thick and heterotopias are common. Ipsilateral enlargement of the lateral ventricle is usual.

Hemimegalencephaly may be associated with overgrowth of the ipsilateral face and sometimes other parts of the body. Moreover, there is a strong association with neurocutaneous disorders, including tuberous sclerosis, neurofibromatosis type I, proteus syndrome, linear sebaceous nevus syndrome, and hypomelanosis of Ito. Apart from these important associations, the embryology of hemimegalencephaly remains to be determined.

The clinical phenotype is variable. Exceptionally, those with it may be neurodevelopmentally normal. More usually they have a range of deficits which may include hemiparesis, visual field defects, learning difficulties, and epilepsy. The epilepsy may be focal or apparently generalized and is often severe and refractory to antiepileptic drugs. Hemimegalencephaly is an important cause of several severe childhood epilepsy syndromes, including Ohtahara, West, and the Lennox–Gastaut syndromes. It is one cause of epilepsy partialis continuans.

Posterior fossa malformations

Malformations of the cerebellum are not uncommon. A few of the better characterized ones are briefly described next. In addition to these, complete absence of the cerebellum, generalized cerebellar hypoplasia, cerebellar dysplasias, and macrocerebellum are all recognized. Clinically, they are usually associated with gross motor delay, various cerebellar signs, and variable general developmental delay. The term ataxic cerebral palsy is often applied. There aetiologies are diverse and encompass, Mendelian genetic disorders, chromosomal abnormalities, single gene defects, neurometabolic disorders, teratogenic damage, and other acquired insults.

Dandy-Walker syndrome comprises complete or partial absence of the cerebellar vermis, with elevation and upward rotation, and cystic enlargement of the fourth ventricle. Hydrocephalus is common. In some, but not all, of those affected there is obstruction of the exit foramina of the fourth ventricle. Dandy-Walker malformation can be an isolated finding, or can be accompanied by other malformations, particularly of the posterior fossa and agenesis of the corpus callosum, and with problems outside the CNS. Presentation with raised intracranial pressure is common. Cerebellar signs and intellectual impairment are common, but not constant.

Dandy-Walker syndrome can be a manifestation of several rare autosomal disorders, various chromosomal abnormalities, or else can be isolated. Certain specific gene mutations giving rise to it have been described in individual families.

Joubert syndrome (**Fig. 84.10**) is a genetic disorder whose most characteristic features are cerebellar vermis hypoplasia or dysplasia, prominent superior cerebellar peduncles, a deep interpeduncular fossa (giving the characteristic molar tooth appearance radiologically), and an abnormally shaped and rostrally displaced fourth ventricle. There may be an associated occipital meningocele and

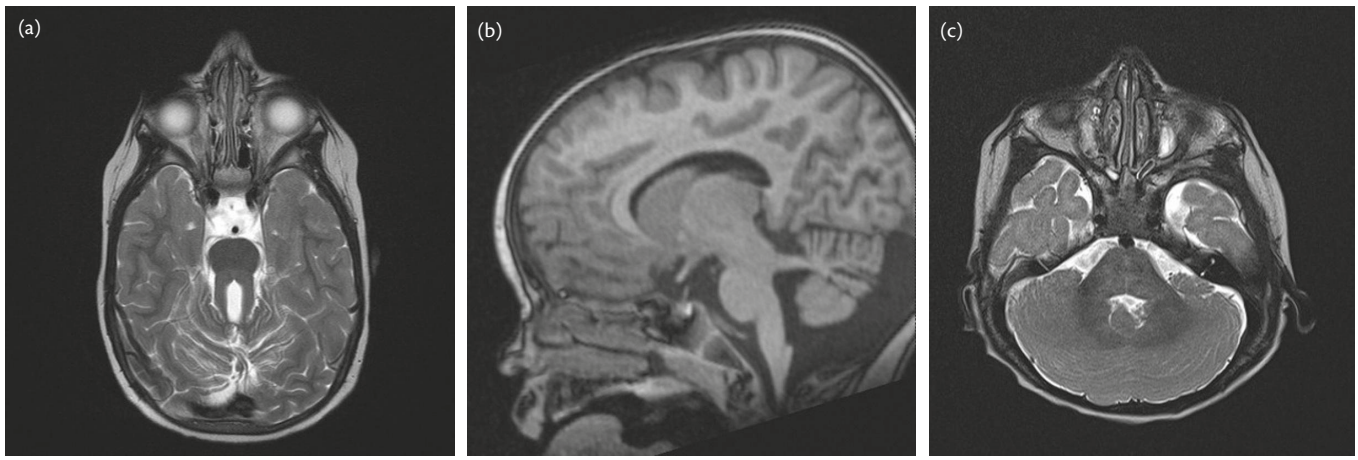

Fig. 84.10 Axial T2 (A) and Sag T1 (B) demonstrate Joubert syndrome, note the characteristic 'molar tooth' appearance on the axial T2 imaging secondary to thickening of the superior cerebellar peduncles and the rostral displacement of the fourth ventricle appreciated on the sagittal imaging, in addition to inferior vermian hypoplasia. (C) Axial T2 shows absence of the midline vermis and fusion of the medial cerebellar hemispheres consistent with rhombencephalosynapsis.

extra-CNS problems, notably retinal dystrophy and renal problems, including nephronophthisis. Affected infants are generally floppy and in early-life abnormal breathing patterns with alternating tachypnoea and apnoea is characteristic. Later oculomotor dyspraxia develops.

The disorder is usually autosomal recessive, and more than 20 mutated genes have been described as giving rise to it. These affect ciliary function, and the disorder is often classified as a ciliopathy.

Rhombencephalosynapsis is a rare malformation with congenital absence of the vermis, and fusion of the medial sides of the cerebellar hemispheres and of the dentate nuclei. It is usually an isolated malformation, but may be accompanied by other midline defects. In addition, there is an association with X-linked hydrocephalus. The clinical picture is dominated by cerebellar signs; cognitive impairment is variable. It is thought to be genetic in origin, but is usually sporadic, although Mendelian inheritance is reported.

Giant cisterna magna, seen as an incidental finding in around 1% of computed tomography (CT) and MRI brain scans, refers to non-pathological prominence of the retrocerebellar cerebrospinal fluid (CSF) space. There should be no associated cerebellar abnormalities.

Encephaloceles

An encephalocele is a herniation of neural tissue within a dural sac through a cranial defect. The failure of the neural tube to close completely is felt to be the embryological basis for this condition. The pathogenesis of encephaloceles appears to be a disturbance in the separation of neural and surface ectoderm during the final part of neural tube formation (Hoving and Vermeij-Keers, 2000). Up to 40% may have chromosomal abnormalities. The incidence is approximately 0.8–4/10 000 live births (Simpson et al., 1984).

The typical presentation is a swelling from the naso-ethmoidal to the occipital region. The subtypes are basal, sincipital (frontal), convexity, and occipital. Children may present with features of nasal obstruction, CSF rhinorrhoea, or rarely with recurrent meningitis especially with lesions in the naso-ethmoidal region or skull base. There may be associated hydrocephalus, epilepsy, neurological deficits, or developmental delay.

Antenatal ultrasound and fetal MRI can help to identify the lesion *in utero*. Postnatally, while an ultrasound can give useful information, an MRI scan is helpful in delineating sac contents and any other associated intracranial anomalies such as microcephaly, corpus callosum dysgenesis, Chiari malformation, and arachnoid cysts (Da Silva et al., 2015). The differential diagnosis for a nasal encephalocele include dermoid cyst and the rare nasal gliomas. CT scan with reconstruction is helpful in defining the bony defect.

Treatment depends upon the size, location, and contents of the sac. The key steps are defining the bony margins and the dural defect, replacing normal herniated neural content intracranially followed by repair of the dura and bony cover. Frontoethmoidal lesions may need correction of associated hypertelorism with orbital advancement techniques (Mahapatra, 2011) or other associated cranial defect/deformities besides the encephalocele. Skull base lesions are increasingly being repaired endoscopically with good results (Ma et al., 2015). Attention should be paid to the anatomy of the venous sinuses at the site of the defect as the dural venous sinuses are often closely related to the sac. Surgery may be required on an emergent basis if there is evidence of a CSF leak. Patients may need any associated hydrocephalus dealt with either before or after corrective surgery.

The anterior (i.e. frontoethmoidal) nasal encephaloceles have a much better survival as compared to the occipital lesions. Neuro disability among survivors is high with only 48% having a normal development (Lo et al., 2008). An institutional review of cephaloceles identified several risk factors on univariate tests as significant independent predictors of developmental delay (i.e. presence of associated intracranial abnormalities, hydrocephalus, seizure disorder, microcephaly, and presence of brain tissue within the malformation). Of these hydrocephalus and intracranial abnormalities carried the most cumulative predictive effect for a poor developmental outcome). Location of the lesion, however, was not a significant factor (Lo et al., 2008). In another institutional review by Da Silva et al hydrocephalus was associated with neurological deficit

in multivariate models. The location of the lesion again was not a significant factor in the incidence of hydrocephalus or neurological deficit. The presence of hydrocephalus resulted in a far worse neurological outcome in this review.

Neurosurgical considerations

Children with cerebral malformations often have complex neurodisabilities and a multidisciplinary approach is essential. Coordinating care is often most appropriately done by a neurodisability consultant. In addition, it is essential to consider if there are or may be extraneurological problems, and to involve appropriate specialists. This is exemplified by the endocrine abnormalities which accompany many midline malformations, and the cardiac problems seen in some patients with nodular heterotopias. The neurosurgeon may be involved in the management of children with brain malformations for three main reasons: to manage raised intracranial pressure; to treat epilepsy; or to help with spasticity management.

As already alluded to, many malformations are associated with hydrocephalus as a near-constant, frequent, or occasional accompaniment. Standard ventriculo-peritoneal shunting procedures are most often used. However, in some malformations, such as the Dandy-Walker malformation, cyst-peritoneal, or combined procedures are advocated by some.

For diffuse and bilateral malformations associated with epilepsy, resective surgery is never an option, but functional procedures, including corpus callosotomy, vagal nerve stimulation, and multiple subpial transections may have a role. Focal cortical dysplasias are a common reason for lobar and multilobar resections, and epileptologists have developed a distinct classification of the focal cortical dysplasias which is useful for surgical planning (Blümcke et al., 2011). Subcortical nodular heterotopias may also be candidates for respective epilepsy surgery. Hemimegalencephaly, is an important indication for hemispherectomy/hemispherectomy, which often presents in very young children as an epileptic encephalopathy. There is growing evidence that surgery may benefit cognitive development, as well as helping to control seizures.

Brain malformations are an important cause of cerebral palsy. With posterior fossa malformations, this is usually of the hypotonic or ataxic type, and is not amenable to neurosurgical interventions. Spasticity, and to a lesser extent dystonia are common in many of the other malformations and treatment with intrathecal baclofen pumps and with selective dorsal rhizotomy may have a useful role to play in carefully selected cases.

Spinal development and spinal dysraphism

Dominic Thompson

Introduction

The term spinal dysraphism encompasses a group of disorders of spinal cord development. Within this group discrete clinical entities are recognized, these differ in their embryological origins, their clinical presentation, and their prognosis. The nomenclature of the spinal dysraphisms is apt to confuse however a simplified classification is presented, based upon the presumed point of origin in embryogenesis and serves not only to simplify terminology but also to direct appropriate investigation and management. It is important to emphasize that while detailed knowledge of embryogenesis based on animal models is available for some of the open neural tube defects this is not so for the closed spinal dysraphisms where the precise developmental defect remains a matter of hypothesis.

Development of the spinal cord

While there is an intimate association between the early development of the vertebral column (mesoderm) and spinal cord (ectoderm) it is the stages of spinal cord development that is germane to the understanding the spinal dysraphisms. For a comprehensive description of vertebral column development see Pang and Thompson (Pang and Thompson, 2010). Development of the spinal cord can be conveniently divided into three stages: gastrulation, primary neurulation, and secondary neurulation.

Gastrulation

The very primitive embryo comprises a two-layer structure, the bilaminar plate. During gastrulation the rostrocaudal polarity of the embryo is established with the formation of a midline groove, the primitive streak. Cells of the outer layer of the bilaminar plate migrate toward the primitive streak and thence between the two layers transforming it into a trilaminar structure. Thus, the three germ cell layers (endoderm, mesoderm, and ectoderm) are established. As the embryo enlarges the primitive streak regresses from head to tail leaving in its wake the notochord. The notochord is fundamental to vertebrate development maintaining not only rostrocaudal polarity but in establishing dorsoventral identity as well. For a transient period, there is a connection across the embryo, via the notochord that allows the amniotic cavity to communicate with the yolk sac, the neurenteric canal. By means of a variety of signalling processes the notochord will induce the overlying ectoderm to form the neural plate and will also begin the process of conversion of presomitic mesoderm to somitic mesoderm, a precursor to vertebral column formation.

Primary neurulation

The ectoderm, which constitutes the dorsal aspect of the early embryo will ultimately give rise to both the central nervous system and integument (skin and its adnexae). During primary neurulation, and under the influence of the notochord the ectoderm begins to fold, the lips at the edges of the fold will meet in the midline. The number of initial meeting points differs between species. A process of zipping up between these 'meeting points' then occurs thus creating the tubular structure of the central nervous system. The ectoderm lateral to the folds will be the future cutaneous ectoderm, these two derivatives of the ectoderm (neural and cutaneous) then separate in a process known as disjunction.

The neural tube formed as a result of primary neurulation will ultimately result in the brain and spinal cord, however only as far as the second sacral segment. The terminal spinal cord, conus medullaris, filum terminale, and cauda equina are formed in a different manner, known as secondary neurulation.

Secondary neurulation

In the tail bud of the embryo is a collection of pluripotent cells known as the caudal cell mass. This mass will contribute to the development of the lower genitourinary tract, the distal anorectal region, and terminal spinal cord. While the details of secondary neurulation are poorly understood in humans it is believed that cells destined to neural differentiation coalesce around a central lumen resulting in the so-called medullary cord, this will become incorporated into the more rostral spinal cord that was formed as a result of primary neurulation. Much of the spinal cord that was formed by secondary neurulation will regress (retrogressive differentiation) resulting in an apparent ascent of the conus, the filum terminale is what remains on completion of this process.

Classification of spinal dysraphism

Various classifications of spinal dysraphism appear in the literature however a classification based upon presumed developmental pathogenesis, while for the most part hypothetical serves as a useful clinical guide (Fig. 85.1). We can therefore look in turn at those dysraphic states that derive from disordered gastrulation, primary neurulation and secondary neurualtion repsectively.

Disorders of gastrulation

Establishment of the three germ cell layers is a principal feature of gastrulation, by the end of this stage the ectodermal layer will form the dorsal aspect of the embryo facing the amniotic cavity. Dysraphic disorders that have their origins in this early stage of development will therefore tend to be ventral to the neuraxis and more likely to be associated with skeletal (mesodermal) and visceral (endodermal) anomalies. In the split cord malformations, it is suggested that there has been duplication of the notochord resulting in two neural tubes. The resulting two hemicords may each lie within separate dural tubes, with an intervening bony spur (type I split cord malformation) or may be contained within a single dural tube separated by little more than a fibrous band (type II in split cord malformation or diplomyelia) (Pang, 1992; Pang et al., 1992). Congenital vertebral body fusions or malformed vertebrae commonly coexist with the split cord malformations and may result in spinal deformity.

The neurenteric canal that traverses the embryo from dorsal to ventral may persist resulting in abnormal connections between the neural and enteric derivatives in the form of neurenteric or enterogenous cysts. These may occur anywhere from the sphenooccipital synchondrosis to the lumbosacral junction but not seen beyond these limits as the neurenteric canal never extended along the full length of the embryo. Again, vertebral bony anomalies typically coexist reflecting involvement of all three germ cell layers.

Disorders of primary neurulation

Impaired primary neurulation results in classical open neural tube defects. Tubulation of the ectoderm has not occurred, the neural tissue is not covered by skin but is either completely exposed, leaking cerebrospinal fluid, or covered by rudimentary meningeal membranes. In the spine this results in myelocele or myelomeningocele. The terms are used interchangeably but are more correctly applied to situations where the neural placode is flush with the surrounding skin (myelocele) or raised up by the accumulation of cerebrospinal fluid (CSF) in the underlying subarachnoid space (myelomeningocele). Open neural tube defects are pan central nervous system (CNS) malformations, in addition to the spinal cord anomaly several structural abnormalities of the brain are usually seen encompassed by the term Chiari II malformation; hydrocephalus will also be present in approximately 80% of cases. It is important to emphasize that the Chiari II malformation and hydrocephalus are not associated with the other (closed) dysraphic conditions.

An important feature of primary neurulation is the separation of cutaneous and neural ectoderm, the process known as disjunction. Depending on whether this process occurs prematurely or incompletely a separate group of dysraphic disorders will result. If the neuroectoderm separates prematurely, before tubulation is complete then the open neural tube becomes exposed to the underlying mesoderm; according to McLone, this is the initial step in the formation of fat on the surface of the placode leading to spinal lipoma. Thus premature disjunction is thought to be the underlying mechanism responsible for dorsal lipoma. It is important to recognize that while this hypothesis is in keeping with the anatomical configuration of dorsal lipoma, it is not compatible with transitional or caudal (terminal) lipomas as these latter types of lipomas are, at least in part, attached to the conus and thus related to secondary neurulation.

If disjunction fails to occur completely then some remnant of the common origin of skin and central nervous system persists. The nomenclature for this group of disorders is particularly confusing,

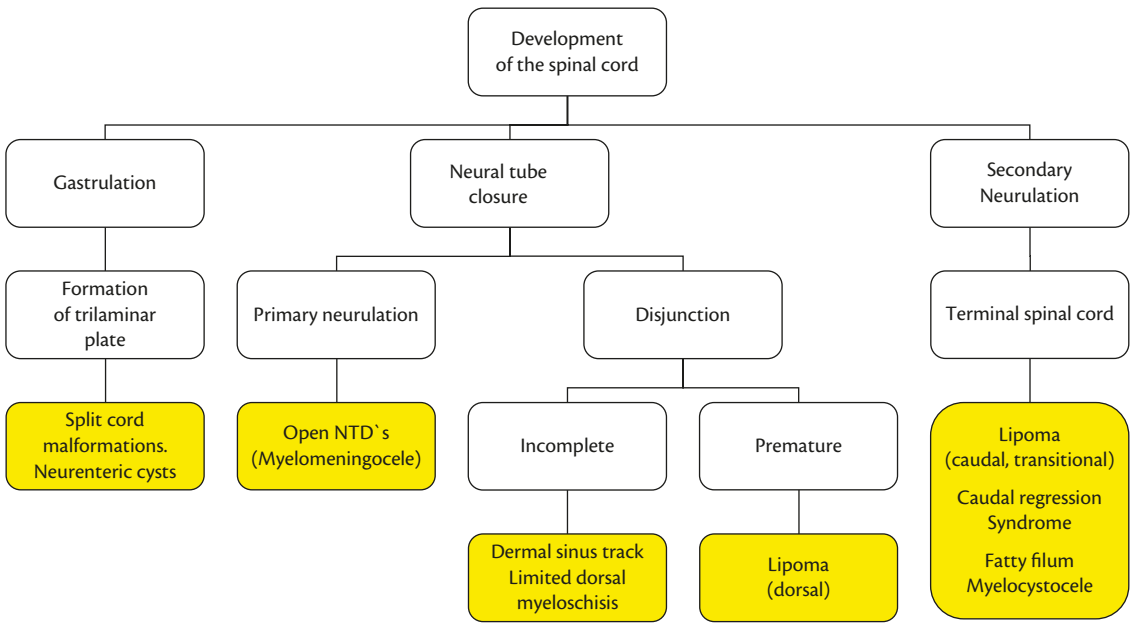

Fig. 85.1 An embryological perspective on the classification of spinal dysraphism.

terms such as meningocele manqué, true and pseudo-dermal sinus track, long and short tethering tracks and, more recently, limited dorsal myeloschisis are frequently encountered. Martínez-Lage et al., 2010; Pang et al., 2013; Thompson, 2013) It is perhaps the histological nature of the neuro-cutaneous connection that best distinguishes the different types of tethering tracks. In limited dorsal myeloschisis (LDM) a tongue of predominantly neural tissue extends from the dorsal aspect of the spinal cord to the overlying skin whereas in dermal sinus track this connection is predominantly epithelial. The distinction is more than semantic as the mode of clinical presentation and neurological differs between the two (see next).

Disorders of secondary neurulation

Many forms of spinal dysraphism involve the conus and cauda equina and thus are thought to result either from aberrant secondary neurulation or impaired regression of the medullary cord. If the medullary cord fails to involute, or does so partially the result is a thickened or fatty filum terminale, when the lipomatous component is larger this is termed a caudal or terminal lipoma, in both instances the conus tends to be functionally intact but situated at a lower level than normal. Transitional lipomas are also likely to have their origins in secondary neurulation. They are termed transitional because they are intermediate in location between the dorsal type and the caudal type, transitional lipomas are intimately related to the conus and the dorsal root entry zone of the elements of the cauda equina, as a result the surgical anatomy is the most challenging of the three lipoma types.

Some disorders of secondary neurulation have much more extensive loco-regional associations reflecting the diverse differentiation of the caudal cell mass. In such situations a variety of congenital genito-urinary abnormalities, encompassed under the term Partial UroRectal Spetal Malformations (PURSMs) including cloacal anomalies, anal atresia, rectovaginal fistula coexist with spinal dysraphism. Sometimes the associations extend beyond the caudal cell mass derivatives including foregut, cardiac, and vertebral disorders, and are grouped under various acronyms including OEIS, VATER, and VACTERL.

In caudal regression syndrome there appears to be complete absence of secondary neurulation, the conus and terminal sacral segments of the spinal cord are absent resulting in a high termination of the spinal cord (Fig. 85.2). The sacrum is dysplastic and there may be an anorectal malformation. By contrast, in the case of terminal myelocystocele the elements of secondary neurulation are present but result in a markedly expanded termination of the spinal cord. The trumpeted end of the spinal cord expands into the subcutaneous tissues resulting in a large midline swelling low in the natal cleft (Fig. 85.3).

Fig. 85.2 Sagittal T2-weighted MRI scan of a child with caudal regression syndrome. There is an absence of the conus medullaris, the terminal spinal cord has a typical truncated appearance, there is also partial sacral agenesis.

Clinical presentation

Broadly speaking there are two presentations of spinal dysraphism, the first is with a cutaneous anomaly overlying the spine, the second is with a neurological, urological, or orthopaedic deficit, the so-called neuro-orthopaedic syndrome. Of course, there is commonly overlap in these modes of presentation.

Cutaneous features of spinal dysraphism

The terms open (aperta) and closed (occulta) spina bifida require clarification. The term 'open' refers to situations in which neural tissue is exposed, often leaking CSF and is thus appropriate for myelomeningocele or rachischisis and for some severe meningoceles, where the neural tissue is covered by little more than rudimentary meningeal membranes. In all other forms of spinal dysraphism the neural tissue is not visible but hidden (occult) due to intact overlying skin. That is not to say that the overlying skin is normal, on the contrary the skin is usually abnormal in some way resulting in the so-called cutaneous stigmata of spinal dysraphism. The presence of any of these should raise suspicion of an underlying dysraphic anomaly:

i. Hairy patch. A focal area of hairy skin in the midline is the classical signature of an underlying split cord malformation and is

Fig. 85.3 Sagittal T2-weighted MRI of an infant with terminal myelocystocele. The terminal spinal cord is 'trumpeted out' due to extensive cystic dilatation of the terminal spinal cord.

easy to distinguish from constitutional hirsutism or lanugo hair of the neonate. As skeletal anomalies frequently coexist in split cord malformations (SCMs), spinal deformity such as scoliosis or kyphosis should be looked for.

ii. Subcutaneous lipoma. This represents the external component of a lipomyelomeningocele. Not infrequently there is a shallow dimple, or 'stork mark' type haemangioma in the overlying skin. Deep to the lipoma it is frequently possible to palpate a defect in the posterior bony elements of the spine. It is via this bony defect that the lipoma is connected to the low termination of the spinal cord. All or part of the lipoma invariably crosses the midline. The lipomas are often large and may vary in shape sometimes having the form of a tail like appendage. Midline lumbosacral lipomas require further evaluation even in the absence of associated neurological signs.

iii. Skin sinus. A skin punctum in the midline may represent the cutaneous end of a dermal sinus track (Fig. 85.4). Confirmatory features are course hairs protruding from the defect or a history of discharge particularly of clear fluid, an intermittent swelling or recurrent episodes of infection. These lesions predispose to intraspinal dermoid formation and infective complications such as spinal abscess or meningitis.

iv. Epithelial 'scar' An area of thinned epithelium, sometimes surround by elevated margins causing a crater like effect is the typical cutaneous feature of LDM. Another skin lesion typical of LDM is a raised dome of skin often with a broad pedicle. These are also referred to as non-saccular and saccular LDM respectively.

It is important to remember that in some instances the condition is truly occult and no external signs are evident. For example, in the case of thickened filum terminale the underlying diagnosis may only come to light once symptoms develop.

Neuro-orthopaedic syndrome

Spinal dysraphism may result in a variable combination of neurological, urological, and orthopaedic symptoms and signs, collectively referred to as neuro-orthopaedic syndrome.

Fig. 85.4 Midline cutaneous punctum typical of dermal sinus track.

Neurological symptoms include pain, which is commonly local spinal pain or exercise induced lower limb pain rather than typical radicular pain, numbness, usually around the feet and distal lower limbs and weakness. Weakness typically affects the musculature of the ankles and feet, and is usually asymmetric.

Orthopaedic manifestations of spinal dysraphism include muscle wasting, joint deformity (for example club feet) and gait disturbance. As with neurological symptoms asymmetry is common, this is particularly marked in split cord malformations where the entire limb or foot is small on the side corresponding to the smaller hemicord. Vertebral malformations including congenital fusions and hemivertebrae will increase the risk of scoliosis. Neuromuscular scoliosis may also occur in high myelomeningocele as a result of asymmetric paraspinal muscle innervation.

Urological disturbance due to involvement of the sacral nerve roots is particularly prevalent in myelomeningocele and spinal lipomas though can occur in any of the dysraphic states. Recurrent urinary tract infection, urinary dribbling, and failure to attain continence are typical clinical features. In the older child, loss of previously attained continence, urgency, or new-onset urinary infections may be indications of neurogenic bladder dysfunction. While faecal soiling due to impaired bowel control may complicate some of the more severe dysraphic states this almost invariably occurs when there is also established neurogenic bladder dysfunction. Isolated symptoms of rectal continence are rarely neurogenic in origin.

Tethered cord

The term 'tethered cord' requires some clarification. In virtually all spinal dysraphism the spinal cord lies at a lower level than normal (L1/L2) and thus might be considered from an anatomical or radiological perspective to be tethered, the exception to this is caudal regression syndrome where the termination of the spinal cord is high due to lack of secondary neurulation. However, not all children with spinal dysraphism have clinical symptoms or signs beyond a skin abnormality, the term tethered cord is therefore probably best reserved to describe the clinical features of the neuro-orthopaedic syndrome occurring in the presence of spinal dysraphism. Tethered cord implies a mechanical aetiology underlying the clinical features in contrast to neural dysplasia; in reality both mechanisms are likely to contribute to the "tethered cord syndrome".

Investigation of spinal dysraphism

Although the timing and specific details of the tests and evaluations required may differ according to the type of spinal dysraphism the general principles comprise accurate radiological definition of the disease entity, establishing a baseline for neurological and urological surveillance and putting in place a management plan that will optimize long-term functional outcome.

Ultrasound

In the first 3 months of life, before the posterior vertebral elements are ossified, it is possible to take advantage of the acoustic window to visualize the terminal spinal cord. Ultrasound can be a useful initial screening test and has been demonstrated to be sensitive to the presence of spinal dysraphism though usually MRI will be required to refine the diagnosis and for surgical planning.

MRI

MRI is the definitive imaging modality for spinal dysraphism. The level of the conus, syrinx formation, and associated vertebral anomalies are well demonstrated. In the closed dysraphic states, it is usually sufficient to image only the spine, in myelomeningocele brain imaging is required in addition to evaluate ventricular morphology and the features of the Chiari II malformation.

Urological evaluation

The two aspects of urological function that require close evaluation in cases of spinal dysraphism are firstly safety of the kidneys and upper renal tract and secondly continence, the ability to store urine and appropriately empty. Ensuring the safety and health of the kidneys is the initial priority particularly for the more severe forms of spinal dysraphism (myelomeningocele, complex lipomas, and caudal regression syndrome). A small volume, high pressure bladder, particularly in the context of urinary infection may predispose to ureteric reflux and renal damage and requires urgent treatment, this might include vesicostomy, continuous or intermittent catheterization, and prophylactic antibiotic treatment.

Achieving 'social' continence is a later priority. Many children with spinal dysraphism will have ostensibly normal bladder function in early childhood. In addition to identifying the 'hostile' bladder, early bladder function tests in infancy are used to try to identify early signs of neurogenic bladder dysfunction or to predict the likelihood of this occurring. In the precontinent child, the interpretation of bladder function and urodynamic studies can be extremely difficult and requires urological expertise.

Physiotherapy

Age appropriate recording of muscle strength is required both to provide an initial assessment of motor deficits and as a means of recording motor function over time as sequential Medical Research Council (MRC) muscle charting can help identify early signs of deterioration. Physiotherapy review is also helpful in identifying deficits in either muscle strength or gait that might be improved by orthotic aids or orthopaedic intervention.

Management of specific dysraphic entities

Myelomeningocele

Myelomeningocele differs from the rest of the spinal dysraphic disorders in being a 'pan CNS disorder'. As a result, structural brain changes and hydrocephalus commonly occur with the spinal anomalies. The characteristic brain abnormalities include downward displacement of the cerebellum, pons, and fourth ventricle, beaking of the tectum, kinking of the medulla, and low-lying hypoplastic tentorium. These features constitute the Chiari II malformation (Geerdink et al., 2012). The Chiari II malformation can be responsible for bulbar insufficiency (breathing and feeding difficulties) particularly in infancy and for high cervical myelopathy in older children. Symptoms of the Chiari II malformation may indicate evolving hydrocephalus or shunt malfunction. It is important to recognize that the Chiari II malformation is exclusive to open neural tube defects and has no association with the Chiari I malformation. Hydrocephalus is reported to occur in up to 80% of cases of myelomeningocele and may be present at birth or may develop following closure of the spinal defect. In recent years shunting rates for myelomeningocele associated hydrocephalus have fallen as in many cases ventricular dilation may stabilize with no apparent adverse consequences (Chakraborty et al., 2008).

While Caesarean section is the most commonly chosen mode of delivery for antenatally diagnosed myelomeningocele there is no clear evidence that normal vaginal delivery poses an additional infection or neurological risk. Surgery to close myelomeningocele should be performed within 48 hours of birth to reduce the risk of infection, reduce ongoing damage to the neural placode and for cosmetic reasons. Shunt placement can be performed at the time of initial closure (if there is severe hydrocephalus) or more commonly deferred until there is clear evidence of progressive hydrocephalus based on serial head circumference measurement or ultrasound.

In the case of closed spinal dysraphism urgent surgery is rarely required. Indeed the indications for surgery and the likely prognosis for many of these disorders is less clear-cut.

Closure of myelomeningocele, surgical considerations

Postnatal repair of myelomeningocele should ideally be performed within 48 hours of birth, so long as the child's clinical condition permits and there are no major contraindications to surgery such as sepsis, coagulopathy, or severe respiratory impairment.

Where there are severe comorbidities such as life threatening respiratory or cardiac conditions then it may be appropriate to consider non-operative management. However even in severe cases of myelomeningocele where the long-term functional prognosis may be poor, surgical closure is generally advised. Untreated lesions tend to become painful, chronically infected, and can present significant nursing difficulties.

Preoperative surgical evaluation

An assessment of the size of the spinal defect and quality of the adjacent skin should be made. Lesions with a diameter of more than 5 cm are unlikely to be amenable to primary closure and the possibility of a local skin flap should be considered. Plastic surgery advice should be considered in this instance. Motor evaluation is important, recording of lower limb muscle strength will indicate the functional level of the myelomeningocele and provides an important baseline for ongoing surveillance. Head circumference measurement and cranial ultrasound are undertaken to anticipate the evolution of hydrocephalus and therefore serial measurement of head circumference and ventricular size need to be instigated. A saline soaked gauze combined with a cling film wrap serves to protect the lesion from desiccation, trauma, and contamination. Prophylactic antibiotics are indicated pending surgical closure. In the absence of signs of infection these are discontinued after surgical closure.

Key surgical objectives

The principal aims of surgery are to replace the spinal cord within the spinal canal, recreate the thecal sac, and provide good quality skin closure to protect the repair and prevent leakage of cerebrospinal fluid.

Key surgical steps

The procedure is performed with the baby in the prone position, pressure areas such as the knees and face need to be protected. The operation is carried out under general anaesthesia. Specific

considerations include ensuring that the child remains warm and well perfused. Excessive blood loss is unusual but may be encountered where large skin flaps have to be raised or when a bony kyphus is removed.

The surgical incision needs to take into account the size and shape of the lesion as well as the potential need to elevate complex skin flaps. Skin laxity, underlying bone anatomy, and proximity to the anus are additional considerations. The neural placode needs to be dissected from the surrounding abnormal skin and membranes. Care needs to be taken to protect the placode, spinal cord, and any underlying nerve roots from further damage during surgical manipulation.

Each of the surgical layers requires meticulous closure in order to prevent leakage of spinal fluid, infection, or wound breakdown due to excessive tension in the skin closure.

Key anatomy

Typically the neural placode will be seen in the centre of the lesion surrounded by the myelomeningocele sac, the latter is comprised of dysplastic meningeal membranes and skin. Once the placode has been mobilized the sac is resected back to normal skin. It is important to ensure that no skin elements are left attached to the placode as these may result in implantation dermoid cysts at a later date.

The posterior vertebral elements (spinous processes and laminae) will be absent at the level of the lesion. Identification of the lowest intact lamina will aid in the identification of the normal dura at the upper end of the lesion. This is the starting point from which the new dural layer can be dissected from the inner lining of the sac.

The multilayer repair begins with neurulation of the placode, rolling up the neural tissue to recreate the terminal spinal cord, this is achieved with interrupted 8/0 monofilament suture. This step is only appropriate if it can be achieved without undue tension at the suture line as this can induce ischaemic injury to the placode. Occasionally abnormal nerve roots are encountered entering the sac these are non-functional and can be removed. A very prominent bony kyphus may have to be resected as this can compromise the skin closure. Additionally neural abnormalities that may be encountered include split spinal cord, hemi-myelomeningocele, and thickened filum.

The edges of the dura are trimmed and then approximated and closed with a continuous suture in an attempt to effect a watertight closure. Where there is concern about the integrity of the dural closure the repair can be reinforced by elevating fascial flaps from the adjacent dorsolumbar fascia.

Postoperative care

Following surgery, the child is nursed in the prone or lateral position to avoid pressure on the surgical wound. The wound should be monitored for signs of infection or CSF leakage.

The head circumference is measured daily and plotted on a head circumference chart. Serial cranial ultrasound scans are used to monitor ventricular size. Progressive ventricular enlargement or signs of raised intracranial pressure require placement of a ventricular shunt.

Urological review to assess the upper and lower urinary tracts is essential prior to discharge. Lower limb deformity, particularly ankle and foot deformities such as talipes should be evaluated and a management plan formulated by orthopaedic surgeons and physiotherapists.

More common complications include wound infection where proximity to the nappy area with risk of wound soiling increases the risk. Dressings should be changed as soon as soiled. Occlusive dressings may help protect the wound from this complication. Local necrosis and wound breakdown can occur due to excessive tension at the suture line.

CSF leakage through the surgical wound may occur due to local factors such as wound breakdown or due to the development of hydrocephalus. CSF leakage is associated with a high rate of infection and requires urgent treatment. CSF may also collect beneath the skin causing local swelling. It is more likely where there has been extensive undermining of the skin leaving a large dead space. In such a scenario a wound drain placed at surgery can help reduce this risk. Pseudomeningocele may also occur due to hydrocephalus.

At least 50% of children who have undergone myelomeningocele closure will develop hydrocephalus requiring treatment. Signs of hydrocephalus include increasing head circumference, tense fontanelle, splaying of cranial sutures, 'sunsetting' eyes or progressive ventricular dilation on ultrasound. Treatment requires placement of a ventricular shunt.

Less common complications include brainstem dysfunction. Radiological features of the Chiari II malformation can be found in most children with myelomeningocele; however, only a minority will develop symptoms of brainstem dysfunction. Bulbar symptoms and signs in the neonatal period include apnoeas, aspiration, and feeding difficulties. These findings may be precipitated by untreated or inadequately treated hydrocephalus. Hydrocephalus should be fully treated before considering hindbrain decompression.

Progressive worsening of lower limb deficits following surgical repair of myelomeningocele can be due to syringomyelia. This is a rare early complication, it can occur later in childhood as a manifestation of untreated hydrocephalus or shunt malfunction.

Lipomas

The spinal lipomas are an anatomically complex form of spinal dysraphism and perhaps the most controversial in terms of surgical management. Three types of spinal lipoma are recognized, dorsal, transitional, and caudal (terminal), based on the point of attachment to the lipoma above, at, or below the conus medullaris. A fourth, chaotic type has recently been described in which the lipoma extends ventral to the spinal cord and nerve roots. The surgical management of dorsal and caudal types of lipoma tends to be more straightforward since involvement of the conus and cauda equina is less thus reducing risk to sphincter innervation. Transitional lipomas represent a significant surgical challenge and are also the group with the highest rate of long-term morbidity (**Fig. 85.5**).

Up to one-third of cases of lipoma that present in infancy are ostensibly asymptomatic with no features of the neuro-orthopaedic syndrome, presenting solely with a lumbosacral subcutaneous mass. It is now recognized that the natural history for spinal lipomas is perhaps more benign than hitherto considered (Kulkarni et al., 2004; Pang et al., 2009; Pang et al., 2010; Wykes et al., 2012; Thompson, 2013). This has led many to question the efficacy of conventional untethering surgery, particularly in asymptomatic cases given the disappointing long-term results reported in many surgical series. The essence of the current surgical controversy surrounding lipomas is twofold; firstly, is there a role for prophylactic spinal cord tethering? and secondly, whether more recently described radical

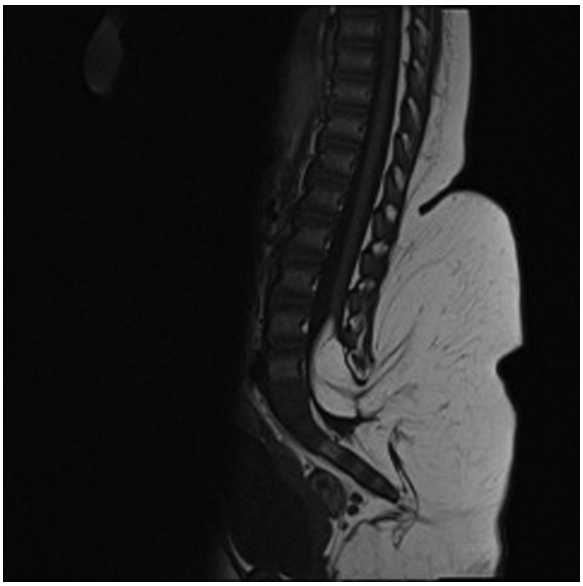

Fig. 85.5 Sagittal T1-weighted MRI of the lumbosacral spine showing a complex transitional type spinal lipoma. The spinal cord is low lying, the lipoma is continuous with a large subcutaneous component of the lipoma via a defect in the posterior sacral elements.

surgery techniques, guided by electrophysiology confer a better long-term prognosis? In attempting to resolve these controversies the following, generally accepted facts need to be taken into account.

1. Up to half of unoperated lipomas will show evidence of neurological or urological deterioration in the course of follow-up. While transitional lipomas seem to be at particular risk this is not reflected in all studies and currently there are no clear predictive features for deterioration that can be identified at the time of initial diagnosis.
2. Surgery for lipoma has a not insignificant risk. These risks include new neurological or urological deficits in at least 5%, and wounded complications such as CSF leakage in up to 20% cases.
3. Conventional untethering surgery techniques are associated with a high rate of late deterioration. The precise rate varies between series but seems comparable to the rate of deterioration in unoperated cases.
4. While pain often responds well to untethering surgery, established neurogenic sphincter disturbance is infrequently improved.
5. The precise mechanisms underlying deterioration remain unclear, specifically the relative contributions of mechanical tethering and underlying neural dysplasia.

Studies by Pang and colleagues have suggested that a more radical approach to the initial untethering is associated with long-term outcomes that are better than either natural history or conventional untethering (Pang et al., 2009; Pang et al., 2010). The principles underlying their technique are near-total resection of the lipoma guided by intraoperative electrophysiological monitoring and mapping, meticulous reconstruction of the neural placode and expansion duraplasty. Their exceptional results are yet to be reproduced in other centres but likely represent a major advance in the treatment of this condition. It is perhaps too early to recommend this technique as a standard of care particularly in asymptomatic patients. Taking the just-featured arguments into consideration our current policy is to carefully monitor asymptomatic children with regular neurological and urological evaluations reserving radical surgery for cases of new or progressive deterioration. Initial evaluations are carried out 6-monthly until urinary continence is achieved and annually thereafter. Serial MRI is not required unless there is evidence of deterioration (Fig. 85.6).

Principles of lipoma surgery

Key surgical objectives

There are three main objectives in complex lipoma surgery, firstly to detach the spinal cord and the associated lipoma from the surrounding tissues, secondly to resect the lipoma from the terminal spinal cord and finally to reconstruct the terminal spinal cord and thecal sac in such a way so as to reduce the risk of re-tethering.

Given the anatomical complexity of these lesions the risk to existing neurological and particularly urological function is not insignificant and therefore it is strongly recommended that intraoperative neuro-physiological monitoring be used. The monitoring consists of a combination of motor evoked potentials (MEP) to evaluate the integrity of the motor pathways and nerve root mapping to aid the identification and preservation of functional nerve roots particularly those to the sphincters. The muscle groups chosen for monitoring and mapping include quadriceps (L4), tibialis anterior (L5), gastrocnemius (S1), abductor hallucis (S2), and anal sphincter (S3 and S4). This ensures that each of the lumbosacral levels is monitored.

Key surgical steps

The initial step in surgery is to locate the defect in the lumbosacral fascia through which the lipoma protrudes. A paraspinal muscle reflection is now carried out to expose the intact laminae immediately rostral to the defect in the fascia. A laminectomy is performed exposing the underlying dura, the extent of the laminectomy should be sufficiently high to permit access and visualization of the normal spinal cord immediately above the attachment of the lipoma. The lipoma passes through a defect in the dura en route to its attachment to the spinal cord, this defect may be quite eccentric and further lateral bone removal is often required such that normal dura can be seen around the entire circumference of the neck of the lipoma. Under the operating microscope the dura is now opened, beginning over normal spinal cord, and continuing around the neck of the lipoma on either side. It is important to identify and protect any underlying nerve roots at this point—nerve root stimulation and mapping facilitate this. On completion of the dural opening the spinal cord and attached lipoma are now free of any surrounding attachment.

The next phase of the operation is to resect the lipoma. The dorsal root entry zone needs to be identified on each side as this will delineate the lateral extent of the lipoma resection. Using sharp dissection, the lipoma is resected from the underlying spinal cord revealing the fibrous 'white plane' at the neural placode. Repeated MEP measurements are taken during this part of the operation.

The final stage of the operation begins with neurulation of the spinal cord, this is done with 8/0 monofilament suture. The thecal sac now has to be reconstructed in such a manner as to create a generous CSF space around the terminal spinal cord. A dural graft is

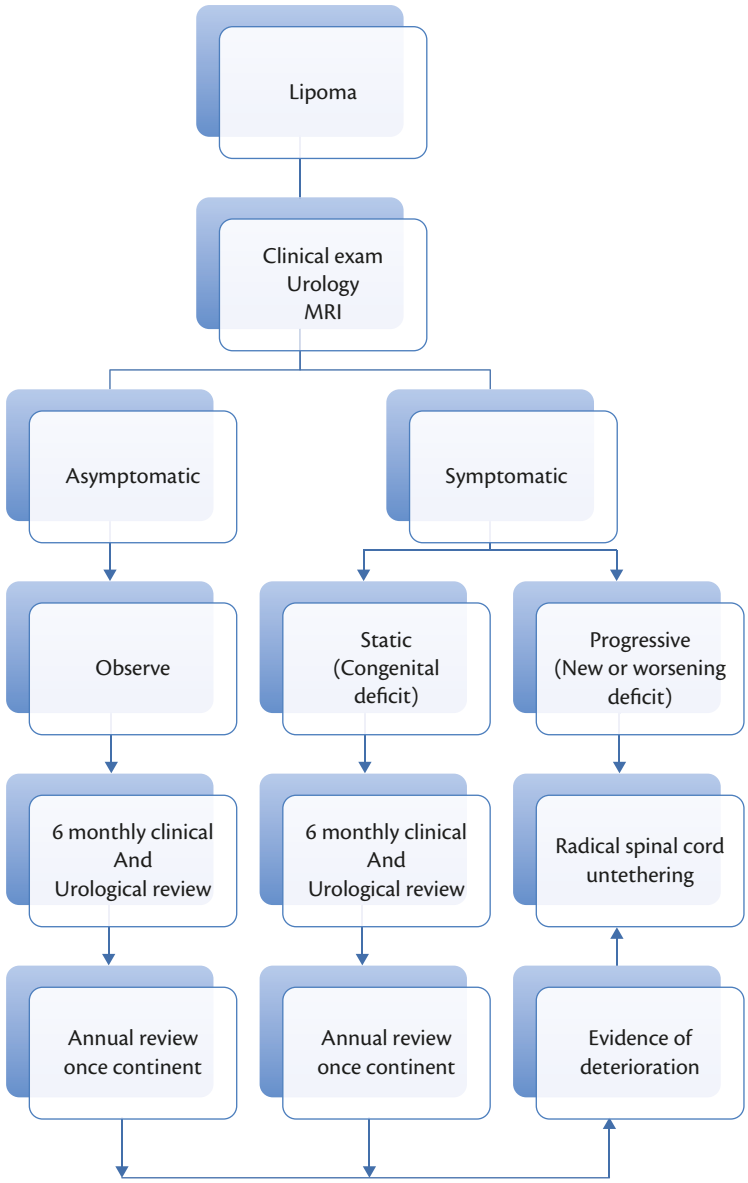

Fig. 85.6 Institutional-based algorithm for the management of spinal lipomas.

cut to the exact dimensions of the dural defect and then secured in place with a continuous non-absorbable suture to provide a watertight closure. The overlying musculofascial and skin layers are then closed meticulously to reduce the risk of any CSF leakage or wound complication.

Dermal sinus tracks and LDM

The disorders of disjunction are associated with risks of infection (spinal abscess or recurrent meningitis), inclusion cyst formation (dermoid or epidermoid) and spinal cord tethering (Thompson, 2013). The risk varies according to the specific diagnosis for example true dermal sinus tract with CSF leakage has a high rate of infection complications while LDM is more prone to neurological complications. For the child presenting with such complications, there is a clear indication for surgery. In a child presenting with a spinal abscess, usually an infected dermoid, initial surgical management is best limited to pus drainage and aggressive antibiotic treatment deferring definitive surgery until the infection is adequately treated. Even where there have been no complications, a child presenting with the typical cutaneous stigmata of dermal sinus or LDM should undergo surgery as the surgery has low risk and the long-term prognosis is good.

The operative procedure for dermal sinus or LDM entails excision of the cutaneous anomaly, identifying the underlying stalk and then tracing this through the deep tissues, into the intradural compartment, and finally excising the attachment to the spinal cord or conus. MRI may underestimate the intrathecal extent of the lesion and so intradural exploration (sometimes requiring three- or four-level laminectomy) is required in almost all cases.

Thickened filum

This is the mildest of the dysraphic anomalies and inevitably there is an overlap with normal variants. Most authorities would agree that when the filum is thickened (at least 2 mm in diameter) and when

the conus lies significantly lower than the normal level (L1/L2) there is at least the potential for damage to occur due to tractional forces as the child grows. Where there are features of the neuro-orthopaedic syndrome then the decision to operate is clear-cut, though even in asymptomatic or borderline cases since the surgical morbidity is extremely low and given the low likelihood of re-tethering prophylactic intervention can be justified.

In the young child the surgery can be performed through a simple fenestration of the ligamentum flavum without recourse to laminectomy. The filum is identified and sectioned under the operating microscope. Almost invariably there is a vessel lying within the filum, this requires explicit coagulation prior to sectioning to avoid the risk of ongoing bleeding after the cut ends have retracted out of the operative view.

Split cord malformations (SCM)

In the type I SCM (diastematomyelia) there is a bony spur lying between the two dural tubes each containing a hemi cord. Symptoms can include progressive pain, weakness or muscle wasting due to differential growth of the vertebral column and spinal cord, progressive spinal deformity is also a risk either due to tethering or by virtue of the associated vertebral anomalies (Fig. 85.7). Many of these children will require spinal orthopaedic procedures for deformity and this represents an additional indication to operate to reduce the risk of tractional damage during scoliosis correction.

The surgery for type I SCM necessitates removal of (frequently abnormal) laminae to expose the spur. The spur is then removed by the combination of rongeur and drilling. The base of the spur may be broad and care is required to avoid injury to the adjacent neural tissue. The dural sheath around the bony spur is then removed and the posterior dura reconstructed leaving the two hemicords in a single compartment. Closure of the ventral dura is not necessary.

Fig. 85.7 3D CT scan of the lumbosacral spine in a case of type I split cord malformation demonstrating the associated bony malformation. The posterior spinal elements are deficient, there are anomalies of the vertebral bodies resulting in deformity and the midline bony spur is evident.

The surgical anatomy of the type II SCM (diplomyelia) is generally more straightforward. The dura is opened along the length of the split cord to identify and remove any intervening fibrous bands. In the author's experience the type II variety may have a very indolent course and such cases can often be safely observed in the absence of symptoms.

Terminal myelocystocele

This rare complex disorder of secondary neurulation will not uncommonly occur in the context of very major urogenital and anorectal malformation. These skin-covered cystic expansions of the terminal spinal cord lie low in the natal cleft and can become extremely large making nursing care difficult and compromising the overlying skin. Early motor deterioration is well recognized in this condition and so early repair is usually recommended. Intraoperative electrophysiological mapping can help determine the lowest level of functional neural tissue, the expanded dysplastic tissue distal to this is then removed and the reconstruction both of the terminal thecal sac and overlying skin can then be performed.

Prognosis and prevention

The prognosis for spinal dysraphism varies according to the specific dysraphic entity, in general the prognosis is dependent upon on the neurological, urological, and orthopaedic status at the time of presentation, as well as the presence of coexisting congenital anomalies. Except for the most minor conditions such as thickened filum, children with spinal dysraphism are ideally followed up in the context of a multidisciplinary team as these children often have complex and changing functional needs through childhood in particular related to mobility and continence. There is often significant psychological morbidity related to issues such as self-image and sexuality, particularly in adolescents. From the neurosurgical perspective one of the main aims of follow-up is the early detection of new or progressive symptoms and signs that might herald the onset of re-tethering.

For children with myelomeningocele there is the additional burden of hydrocephalus and bulbar disturbance which will require lifelong neurosurgical surveillance.

The role of folic acid in the prevention of neural tube defects relates only to open and neural tube defects (encephalocele and myelomeningocele), there is no evidence that folic acid confers any risk reduction for closed spinal dysraphism.

Controversies

There are many controversial issues surrounding spinal dysraphism. Many of the conditions are rare which both constrains institutional experience and the ability to permit large scale clinical studies. In many instances the true natural history of the asymptomatic state is poorly documented and management is based on limited evidence. This is particularly so for spinal lipoma where the role of prophylactic intervention is far from proven. It is important that the results of radical surgical untethering are replicated in other studies. It will then be important to try and identify or risk stratify those cases that might benefit from early radical surgery.

In utero surgical repair of myelomeningocele has been demonstrated in a randomized clinical control trial to have superior outcomes to standard postnatal repair. Opponents are critical of the trial conclusions and ethical concerns are raised in respect to the maternal risk as well as to the impact on future pregnancy. It is likely that this surgery will become more widely offered and the surgery refined utilizing minimally invasive techniques.

Conclusions

Spinal dysraphism comprises a heterogeneous group of congenital spinal anomalies. Although in many cases the details are currently incomplete these disorders are best understood from an embryological perspective. Early and precise anatomical diagnosis is essential in determining prognosis and formulating and appropriate management plan.

Surgery for spinal dysraphism can be extremely complex and decision-making should be guided the principle of optimizing long-term functional outcome. Intraoperative neurophysiological monitoring and mapping are becoming indispensable tools in the surgery of these conditions.

The importance of multidisciplinary team care in the management of these lifelong conditions cannot be overstated.

Craniofaciosynostosis

Syndromic and non-syndromic craniofacial anomalies

Federico Di Rocco, Pierre-Aurelien Beuriat, and Eric Arnaud

Introduction

Craniosynostosis is a condition in which there is a premature fusion of one or more sutures of the skull with a modification of cranial growth and an abnormal skull shape. The shape is specific to the suture involved so the diagnosis is essentially clinical.

The genetic causes remain largely unknown. Molecular researches have identified several mutations.

Complications can result to the deformation of the skull but also abnormal facial morphology. Cerebellar tonsillar prolapse, hydrocephalus, intracranial hypertension, insufficient eye protection, respiratory obstructions, and orthodontic problems are the most common.

Several factors play a role in the surgical indications. The aim of the surgery is functional and cosmetic. Techniques have evolved from simple strip to total calvarial and supraorbital remodelling, osteogenic bone distraction, and endoscopic procedures. In all craniosynostosis, long-term follow-up is mandatory because there is a risk of secondary synostosis which exists independently from the originally affected suture.

Definitions

The term craniosynostosis (CRS) derives from *cranio:* cranium, *syn:* together and *ostosis:* bone formation. It is a condition in which there is a premature fusion of one or more sutures of the skull with a modification of cranial growth and an abnormal skull shape. Normally, skull bone growth is perpendicular to the suture, but in CRS the direction of growth becomes parallel to the suture and there is an abnormal growth of the rest of the skull to compensate for the lack of development of the affected part. Moreover, as bone growth is directly linked to brain growth, the closure of one or more sutures leads to an abnormal brain growth so that the modification of the shape is the result of both the compensatory growth but also the alteration of the brain.

CRS shape is specific to the suture involved. The elongation of the skull in a boat shape is due to the premature synostosis of the sagittal suture (scaphocephaly) (**Fig. 86.1**). A growth restriction of the frontal bones in triangular or wedge shape is due to the premature closure of the metopic suture (trigonocephaly) (**Fig. 86.2**). A skew head due to unilateral coronal or lambdoid synostosis is an anterior (**Fig. 86.3**) or posterior plagiocephaly, respectively. It is very important to differentiate, the positional posterior plagiocephaly in which the suture is still opened from a true CRS with early closure of a unilateral lambdoid suture. In positional plagiocephaly the ear on the affected side is often displaced anteriorly but remains at the same craniocaudal level whereas in case of true synostosis the ear on the affected side is deviated toward the fused suture and often tilted inferiorly. When both coronal sutures are closed (brachycephaly), there will be a lack of forward and backward growth with an impression of a short head. The term oxycephaly is used when the coronal and the sagittal sutures are closed.

CRS can also be differentiated as primary (when the closure is linked to a bony problem) or secondary (when the closure is linked to a problem in brain growth that interrupts the bony development), syndromic (when the CRS is associated to others malformations especially at the facial level) or non-syndromic cases (when the CRS is isolated) and simple (when only one suture is affected) or complex (when multiple sutures are affected) forms.

Epidemiology

The global incidence of CRS is 1:2500 births. It is the most common craniofacial malformation in humans. The most common forms are the non-syndromic CRS (NSC). They represent 80–85% of the cases (Di Rocco et al., 2009). NSC that affect only one suture represent over 70% of all CRS.

Scaphocephaly is the most common type. It represents roughly 50% of all NSC (Lajeunie et al., 1996). Trigonocephaly used to be the third most common CRS after anterior plagiocephaly but its incidence has risen in the last 20 years. It is now the second most common form of NSC. Posterior plagiocephaly is the most rare and accounts for about 3% of NSC.

The sex ratio is in favour of boys for scaphocephaly and trigonocephaly with a male-to-female ratio of 2.5:1 and 3.3:1,

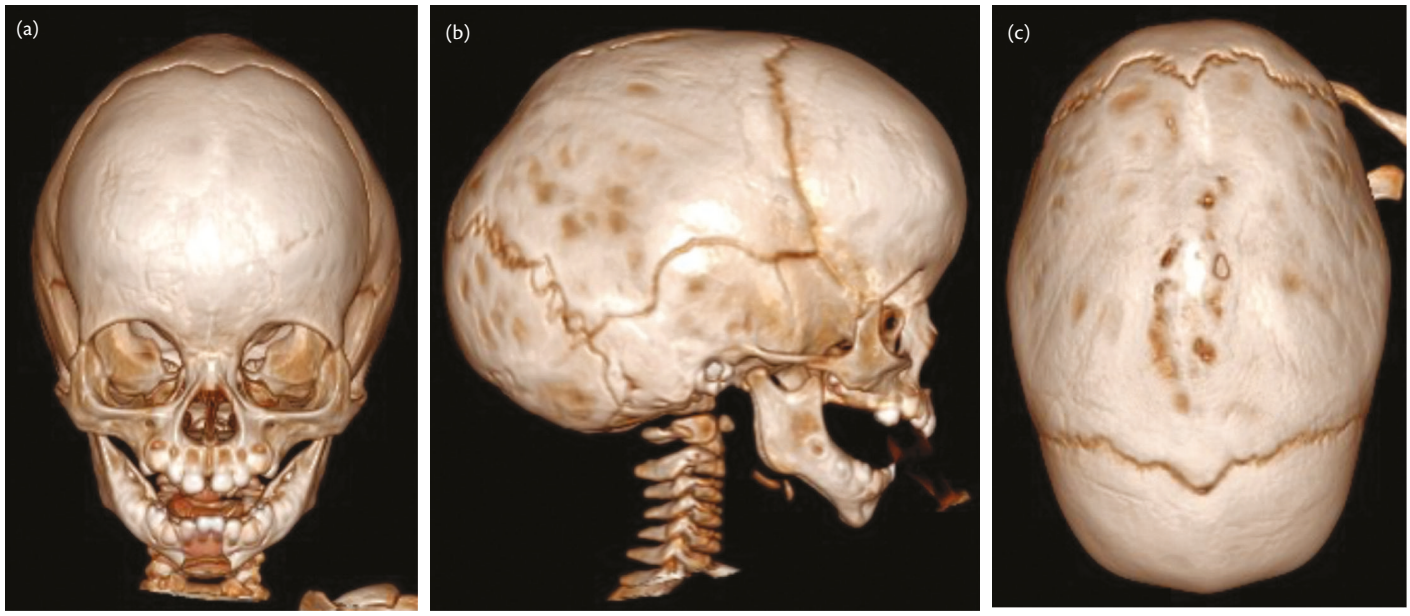

Fig. 86.1 A typical skull CT 3D reconstruction of a 6-month-old boy with scaphocephaly. Note the closure of the sagittal suture causing an anteroposterior elongation of the skull.

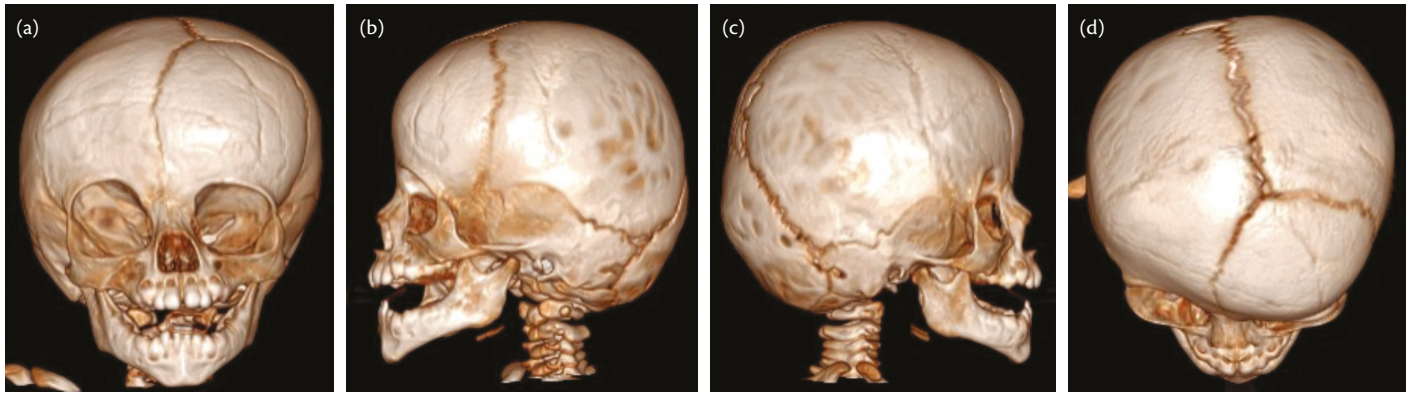

Fig. 86.2 A typical skull CT 3D reconstruction of an 8-month-old girl with a right anterior plagiocephaly. Note the closure of the right coronal suture causing a skew head.

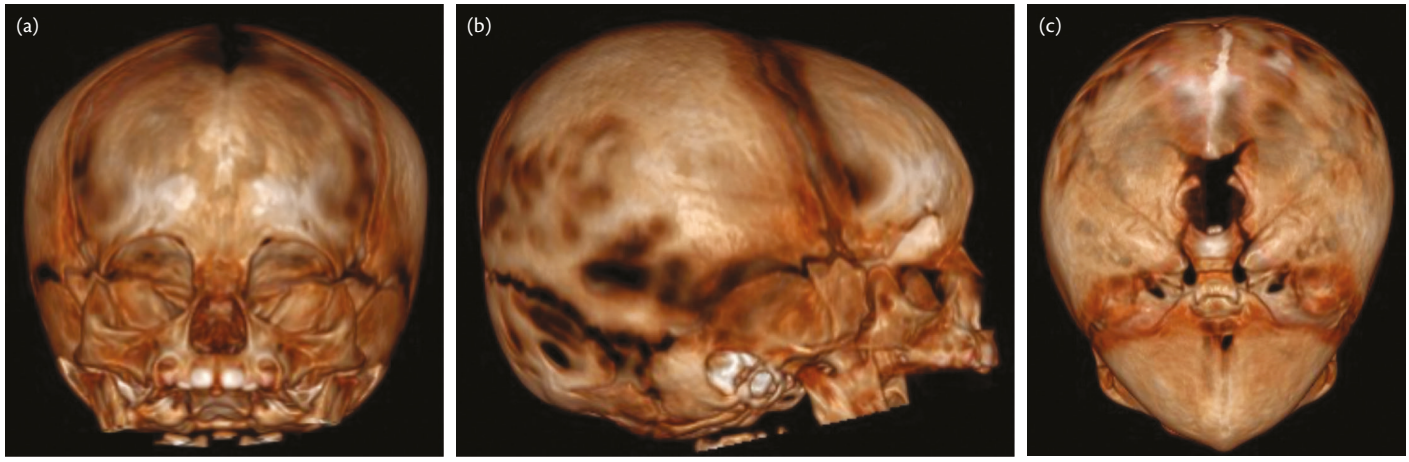

Fig. 86.3 A typical skull CT 3D reconstruction of a 7-month-old girl with a trigonocephaly. Note the closure of the metopic suture causing a triangular forehead.

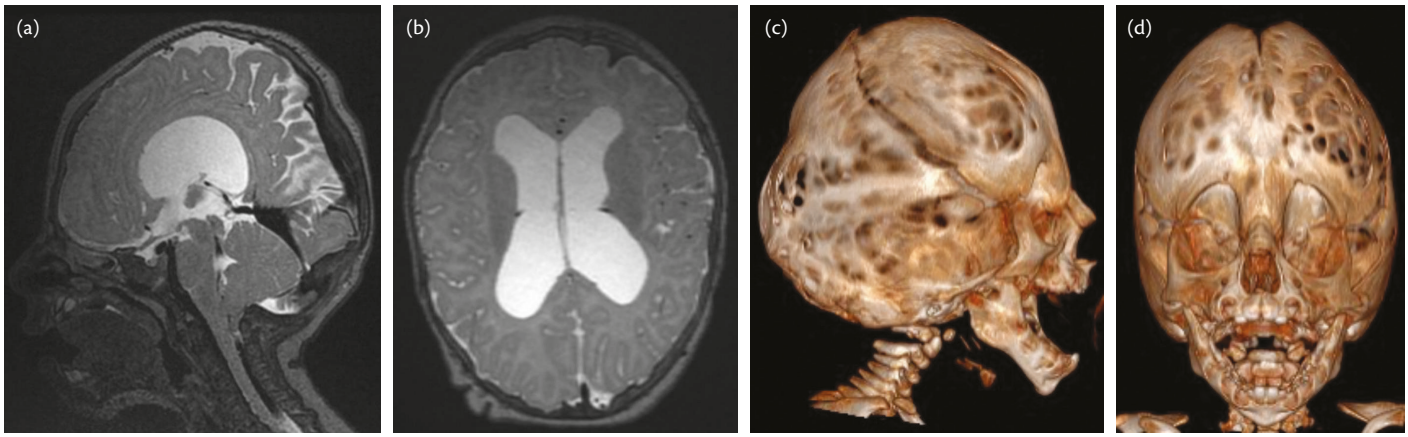

Fig. 86.4 MRI (A, B) and skull CT 3D reconstruction (C, D) of a 19-month-old boy with Crouzon syndrome. Note on the MRI the tonsillar prolapse and the ventricular dilatation. On the skull CT, note the copper beaten skull.

respectively (Lajeunie et al., 1996) while plagiocephaly is more frequent in girls (male-to-female ratio of 1:2.3) (Lajeunie et al., 1996).

Most of the time, NCS are sporadic cases but familial histories may be found in any type of synostosis (Lajeunie et al., 1996).

Syndromic CRS (SCRS) represent 15–20% of all CRS. There are more than a hundred different syndromes but the most common are the Crouzon (Figs. 86.4 and 86.5), Pfeiffer, Apert, Saethre–Chotzen, and Muenke syndromes (Table 86.1).

Aetiology and physiopathogenesis

The genetic causes remain largely unknown. Molecular research has identified several mutations in CRS which involve mostly three of the four fibroblast growth factors (FGFRs) but other genes have been identified such as *TWIST 1, ERF, TCF 12*, and *EFBN1* which are found mostly in SCRS. Mutations are mostly autosomal dominant and a great phenotypic variability exists. Different phenotypes can result from the mutation of a single gene. Appearance can be very different from one patient to another, from subnormal to extremely abnormal. On the contrary similar phenotypes can be generated by several gene defects (Heuzé et al., 2014). In NSC, mutations are rarely found (Wilkie et al., 2007). Other factors, including environmental ones (intrauterine fetal constraint, unhealthy prenatal maternal lifestyles, perinatal hypoxemia) are considered to favour the development of a CRS.

From a functional point of view, many complications can result from a CRS. They are more common in the SCRS where several sutures are involved. Not only the deformation of the skull but also the abnormal facial morphology may lead to complications making collaboration between plastic, craniomaxillofacial, and neurosurgeons essential in the management of these complex pathologies.

From the neurosurgical point of view, one of the most common brain malformations is cerebellar tonsillar prolapse (CTP) (sometimes referred to as Chiari I malformation). CTP is considered the consequence of a disproportion between the small volume of the posterior fossa and the volume of the cerebellum favoured by the premature closure of the lambdoid and skull base sutures and associated hydrocephalus (Cinalli et al., 2005). CTP is very frequent in Crouzon syndrome and Pfeiffer syndromes (Cinalli et al., 2005). Though it is usually asymptomatic, sometimes a posterior decompression may be needed.

Increased intracranial pressure (ICP) is another point of concern. It is secondary to the decreased intracranial volume due to the synostosis generating a craniocerebral disproportion, to venous flow anomalies due to the stenosis of the jugular foramina and to alterations in cerebrospinal fluid dynamics leading to ventricular dilatation.

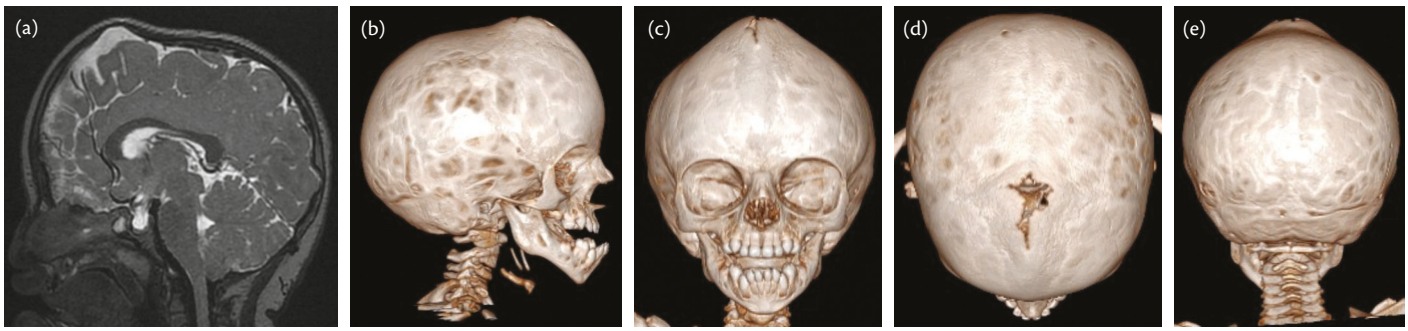

Fig. 86.5 MRI (A) and skull CT 3D reconstruction (B–E) of a 21-month-old girl with Crouzon syndrome. Note on the MRI, the absence of tonsillar prolapse and ventricular dilatation. On the skull CT, note the pansynostosis.

Table 86.1 Features of the most common craniofacial syndromes

	Clinical features	Sutures involved	Genetic findings
Crouzon syndrome	Hypertelorism Beaking nose Proptosis Midface hypoplasia	Coronals Occasional pansynostosis	Mutations in FGFR2 *De novo* or autosomal dominant inheritance
Pfeiffer syndrome	Hypertelorism Proptosis Midface hypoplasia Broad, short, great toes Broad deviated thumbs Brachydactyly	Pansynostosis Cloverleaf skull	Mutation in FGFR2 (95%) and FGFR1 (5%). *De novo* or autosomal dominant inheritance
Apert syndrome	Ocular hypertelorism, Downslanting palpebral fissures Thin upper lip Midface hypoplasia Syndactyly of the hands and feet	Pansynostosis Coronals	Mutations in FGFR2 (S252W and P253R) Mostly *de novo*
Saethre–Chotzen syndrome	Low-set hairline Parrot-beaked nose Ptosis Abnormal ears (prominent crus) Syndactyly	Coronals Metopic or sagittal sutures have been described	Mutations in TWIST1 *De novo* or autosomal dominant inheritance
Muenke syndrome	Mild midfacial hypoplasia Hypertelorism	Coronals	Mutation in FGFR3 (P250R) *De novo* or autosomal dominant inheritance

Hydrocephalus is frequent in Crouzon and Pfeiffer syndromes (Cinalli et al., 2005; Di Rocco et al., 2010). Its physiopathology is complex. It results from a combination between venous flow anomalies and CTP (Cinalli et al., 2005; Di Rocco et al., 2010).

From the craniomaxillofacial surgical point of view, the anomalies in facial morphology and facial growth of CRS may also lead to insufficient eye protection, respiratory obstructions, and orthodontic problems. Respiratory problems are the consequences of upper airway obstruction (Mathijssen et al., 2006) but also the CTP. The main problem linked to this breathing dysfunction is obstructive sleep disorder, which can worsen intracranial hypertension.

Ocular problems result from the chronically increased ICP that lead to visual impairment due to optic nerve compression, atrophy, and the complications of exorbitism (Khong et al., 2006). It is more frequent in SC.

Another very important point to stress is the intellectual, behavioural, and emotional functioning in children with CRS (Maliepaard et al., 2014). The outcome is related to the type of deformity, syndrome, and the associated brain malformation. Apert syndrome has the worst mental prognosis (Renier et al., 1996). It is rare but possible to find mental retardation in Crouzon and Saethre–Chotzen syndromes (Michael Cohen Jr., 2011). It is difficult to demonstrate whether, it is the consequences of the craniocerebral disproportion causing white matter anomalies or due to the direct effect of the genetic mutations on the brain itself (Raybaud and Di Rocco, 2007).

Diagnosis

The phenotype of CRS being specific the diagnosis is essentially clinical.

Prenatal diagnosis of many craniofacial malformations is possible but remains currently rare. The diagnosis is suspected not only on head deformity but also on brain, face, and extremities anomalies. When multiple signs are seen on the ultrasound scan, it is recommended to perform an MRI and an amniocentesis with standard karyotype and molecular genetic testing.

Investigations

After the diagnosis has been suspected by clinical evaluation, further investigations may be needed to assess the associated anomalies.

Plain X-rays, computed tomography (CT) scan, and more recently ultrasound and MR may be used to see exactly which sutures are involved. The morphological alterations of the skull and face can be clearly appreciated on CT 3D reconstructions.

Other investigations can be necessary in SCRS: MRI to evaluate the hydrocephalus, the CTP, and other potential brain malformations; ophthalmological examination to search for papilloedema and signs of raised ICP as well as complications of exorbitism; ear, nose, and throat (ENT) to evaluate the upper airways obstruction; polysomnography study because the presence of apnoea can modify the surgical procedure. The genetic testing for the patient and the family allows correct parental counselling when an underlying mutation is recognized. Finally, neuropsychological follow-up is recommended.

Surgical principles

Several factors play a role in the surgical indications: age of the patient, type of CRS, raised ICP, hydrocephalus, CTP, severity of the respiratory obstruction, degree of cranial hypoplasia, ocular problems as well as mandibular/maxillary, orthodontic, orbital, and facial morphology. The aim of surgery is dual: functional and cosmetic.

At a functional level, the aim is to treat hydrocephalus, prevent intracranial hypertension, mental delay, ocular problems, and

improve respiratory problems. At a cosmetic level, it is to correct the craniofacial dysmorphology to prevent psychological consequences.

Techniques have evolved from a simple strip to total calvarial and supraorbital remodelling. Nowadays, osteogenic bone distraction (Choi et al., 2010) and endoscopic procedures (Jimenez and Barone, 1998) represent interesting alternatives (Sanger et al., 2014). The extent, timing of surgery, and the indications are still elements of controversy. But one should remember that often NSC will undergo surgery for cosmetic reasons only (Di Rocco, 2009). Because it is not possible to predict whose patients will develop neurocognitive impairment, surgery is indicated, irrespective of the cosmetic aspect (Barritt et al., 1981) because the sooner the surgery is performed, the better the outlook is. Moreover, early surgery allows a better correction because the dysmorphism is less pronounced and the bone is more malleable, and it permits the use of the natural brain growth for passive postoperative remodelling. Therefore, these patients should be operated on before one year of age. These surgeries being associated with potentially significant blood losses (White et al., 2015), the timing of the procedure depends mostly on the type of CRS and the weight of the patient according to the planned procedure. In our practice, patients with scaphocephaly are usually operated on before the age of 6 months; for trigonocephaly and anterior plagiocephaly, between 7 and 8 months of age.

In SCRS, the surgical strategy is more complex, several surgical operations are usually necessary. The first surgical procedure to be performed depends on the presence of increased ICP, hydrocephalus, thrombocytopenia (TCP), and breathing problems. If there is a papilloedema, the surgery needs to be done as an emergency.

The classical procedures in SCRS are posterior skull expansion, fronto-orbital advancement, and facial advancement. Posterior skull expansion is usually the first step in Crouzon or Pfeiffer syndromes. Patients affected by these syndromes often suffer from progressive hydrocephalus due to the hypoplastic posterior cranial fossa with secondary crowding of the contained neurovascular structures. Ventricular CSF drainage lowers the expanding force that allows the skull to grow and favours the stenosis. Therefore, a procedure to increase the posterior cranial volume is nowadays recommended initially. It has the effect of decreasing the ICP, restabilizing CSF dynamics, and decompressing the venous structures. Sometimes when a mechanical CSF obstruction is the cause of the hydrocephalus, an endoscopic ventriculocisternostomy may be performed (Di Rocco et al., 2010). Several techniques can be used, from sole posterior craniotomy to a fixed posterior bone flap, using resorbable plates or free-floating bone flap. Another very efficient technique is to perform a posterior craniotomy and add distractors to ensure cranial expansion. Moreover, when a TCP is present, a foramen magnum decompression can be associated in order to decompress the craniovertebral junction. Further procedures will be needed to correct the anterior part of the skull. These surgeries are postponed until later in life to obtain a better and more persisting cosmetic result.

When management of the anterior part of the skull is considered fronto-orbital advancement is the gold standard procedure followed if needed by a facial advancement. The latter should be postponed as much as possible until the age of 11 or 12 years old in order to wait for the end of the last dental eruption. If the facial retrusion is severe and is creating functional (ocular, respiratory, and masticatory) or psychological problems, earlier surgery may be done.

The standard technique for fronto-orbital advancement is a horizontal tongue-in-groove advancement, including an orbital bar osteotomy and advancement. The fixation of the reconstructed elements is done with bioabsorbable plating systems.

When it comes to facial advancement, the Lefort III type described by Tessier (Tessier, 1967) is indicated. The use of a distraction technique permits a gradual expansion through an osteogenic distraction procedure (Iannetti et al., 2006).

In cases of severe exorbitism and upper airways obstruction, Tessier developed a one stage surgery with the combination of fronto-orbital and facial advancement (Tessier, 1971). Frontofacial monobloc advancement is, in most cases, associated with an osteogenic distraction procedure because it has been shown that it lowers the complications of this high-risk procedure (Arnaud and Di Rocco, 2012).

Finally, in older children and adolescents, the appearance of the patient, when facial growth is almost completed, may be further improved by cosmetic and orthognathic surgery.

In all CRS, long-term follow-up is mandatory because there is a risk of secondary synostosis which exists independently from the originally affected suture.

Controversy section: Minimally endoscopic procedures (MEP) for CRS

A controversy exists between the strip craniectomy and cranial vault remodelling in NSC.

For: As whole-vault cranioplasty is associated with important blood losses several techniques to minimize blood loss and transfusion have been designed. Among them MEP (endoscopic strip craniectomy followed by moulding cranial orthosis for several months) has been shown to have minimal blood loss (Jimenez and Barone, 2012), allow a reduced hospital stay, and be cost-effective (Chan et al., 2013). Last but not least, this procedure is possible for almost every type of single suture CRS (Jimenez and Barone, 2012).

Against: Results rely on the postoperative application of a helmet. The orthosis might reduce the cranial growth, is expensive and laborious. Incomplete remodelling is possible even with the orthosis (Sauerhammer et al., 2014). Finally, recent studies suggest that better long-term intellectual outcomes are achieved with whole-vault cranioplasty (Hashim et al., 2014).

Special considerations in paediatric head and spinal trauma

Andrew Kay, Desiderio Rodrigues, Melanie Sharp, and Guirish Solanki

Incidence and epidemiology of paediatric trauma

Traumatic brain injury (TBI) is the most common cause of death or disability in childhood.

It is estimated that in the United Kingdom approximately 150 000 children have a head injury but less than 14 000 attend hospital every year with TBI. The overall mortality rate is 9 per 100 000 accounting for 1% of all childhood deaths (Royal College of Surgeons, 1999).

The main mechanisms of paediatric TBI are dependent on age. In those under 2 years, non-accidental head injuries (NAI) and ground level falls are the most common. From 2 to 4 years, falls predominate. Between age 4 and teenage years, falls or road traffic collisions (RTC) are the most common. In teenagers, RTCs are the main cause of TBI.

The type of injury also differs between adult and paediatric TBI. Skull fractures and extradural haematomas are more common in paediatric patients.

Paediatric spine fractures account for a minority (1–3%) of all paediatric fractures. Around 60% are cervical spine injuries, and while only 3% of these will present with neurologic deficits, spinal cord injury (SCI) in children remains a catastrophic event and every attempt should be made at decreasing the extent and severity of the injury as well as the complications following the injury (Eleraky et al., 2000; Brown et al., 2001).

In children under the age of 8 years, as many as 87% of injuries occur at C3 or above. Injuries below C3 are more common in older children with an adult pattern of injury. With regards to age the commonest types of fracture in the very young are C1 ring and C2 (Hangman) fractures, while odontoid fractures are evenly distributed across all ages. Lumbar fractures occur in the older age group.

The causes of injury also depend on the age of the child, infants are injured by birth trauma in the neonatal period or from accidental falls from the parent's arms, cots, settees, or sofas. Children from 2 to 8 years old get spinal injuries from bicycle falls and other road traffic accidents (RTAs). It is reported as many as 25–60% follow an RTA in this age group. Older children sustain spinal injuries from falls and sports injuries.

Pathophysiology of paediatric head injury

The basic response to TBI is similar to adults but there are anatomical and physiological differences unique to the paediatric population including a disproportionately large size of the head with weak neck musculature in neonates and infants which places them at an increased risk from rotational and acceleration/deceleration injuries. Children also have greater elasticity of bone, wide subarachnoid spaces, high water content in the brain, and viscoelastic properties which increase the likelihood of a diffuse axonal injury.

Intracranial pressure (ICP) varies with age. In infants and young children, the normal ICP is under 10 mmHg. In the older child and adult, the normal ICP is 15 mmHg.

Cerebral blood flow (CBF) also shows age-related variation: in infants it is 40 ml/100 g/min, children 75–110 ml/100 g/min and adolescents, like adults 50 ml/100 g/min.

Head injury management

Early management of all TBI should follow Advanced Paediatric Life Support (APLS), Advanced Trauma Life Support (ATLS), American College of Surgeons Committee on Trauma (1997), and National Institute of Clinical Excellence (NICE) guidelines. (See 'Key references'—NICE Head injury guidelines.)

All children admitted with a head injury should be managed in a major trauma centre with Paediatric Intensive Care Unit (PICU) and paediatric neurosurgery services. Safe and timely transfer is essential.

The Glasgow Coma Score can be applied to children which allows the severity of the injury to be measured. A modified version is acceptable in preverbal children and infants (see **Table 87.1**).

Similar to adults, early head injury management is focused on prevention of secondary injury to the brain mainly from hypoxia and hypoventilation, along with cervical spine immobilization. In severe TBI (GCS less than 8) or where neurological deterioration is

predicted based on the mechanism of the injury and the scan findings, early admission to PICU is necessary.

Indications for intubation reflect those in adults, with an additional indication in uncooperative children who need a computed tomography (CT) scan. Tracheal intubation can be difficult and uncuffed tubes are used in children less than 8 years old.

Indications for ICP monitoring mirror those for adult TBI. Infant ICP can be assessed qualitatively using the anterior fontanelle. The current consensus on the threshold for active lowering of ICP in children is 20 mmHg (Adelson et al., 2003).

Management of ICP is still based on adult data, with focus on adequate oxygenation, ventilation including avoidance of hyperventilation, analgesic sedatives including opiates and midazolam with additional muscle relaxants, surgical intervention (as deemed necessary), and barbiturate coma as second-line therapies. Propofol, which is widely used in adult head injury, is an emulsion and has been associated with metabolic acidosis and high lipid levels in children.

Target cerebral perfusion pressure (CPP) values have not yet been established for infants and young children. A spectrum of 40 mmHg from infant to 70 mmHg as a teenager is considered appropriate.

To date, paediatric trials for decompressive craniectomy have been small. The largest RCT to date with 27 patients showed improved functional outcome at 6 months (Taylor et al., 2001). Longer-term outcomes have not been reviewed. As with adult decompressive craniectomy trials concerns relate to conversion of mortality to increased functional morbidity. Anecdotally the threshold for decompression remains lower among paediatric neurosurgeons in view of the unknown longer-term outcomes.

Phenytoin is more commonly used in paediatric patients with a severe TBI than in adult patients to minimize the incidence of early post-traumatic seizures. Antiepileptic medication is usually given for a 1-week course. Early seizures are much more common in young children and become less prevalent in older children. Early seizures in children are poorer predictors of post-traumatic epilepsy than in adults.

Hypothermia reduces ICP but there is limited evidence about its efficacy and safety in children (see 'Controversies in paediatric trauma' section).

A CT head scan is the scan of choice in TBI. A CT scan of the cervical spine exposes the thyroid gland to ionizing radiation and therefore is not always indicated in mild injury where X-rays may be sufficient. UK hospitals generally follow NICE guideline indications for CT scans (**Figs. 87.1** and **87.2**).

'Clearing' the cervical spine in obtunded children is less easy than in adults because the incidence of ligamentous injuries and spinal cord injury without overt radiological abnormality (SCIWORA) is much higher. MRI scanning is useful in identifying spinal cord signal change, haemorrhage, ligament, muscle, and disc injuries. Acute bone injury is well seen on short tau inversion recovery (STIR) images which can help differentiate acute from longstanding changes. Immobilization with a collar until the child is alert may be unavoidable (Lee et al., 2003).

Paediatric head injury prognosis

A significant proportion of children with TBI die before they reach hospital. The highest mortality is seen in RTA passengers and the lowest in falls (Parslow et al., 2005).

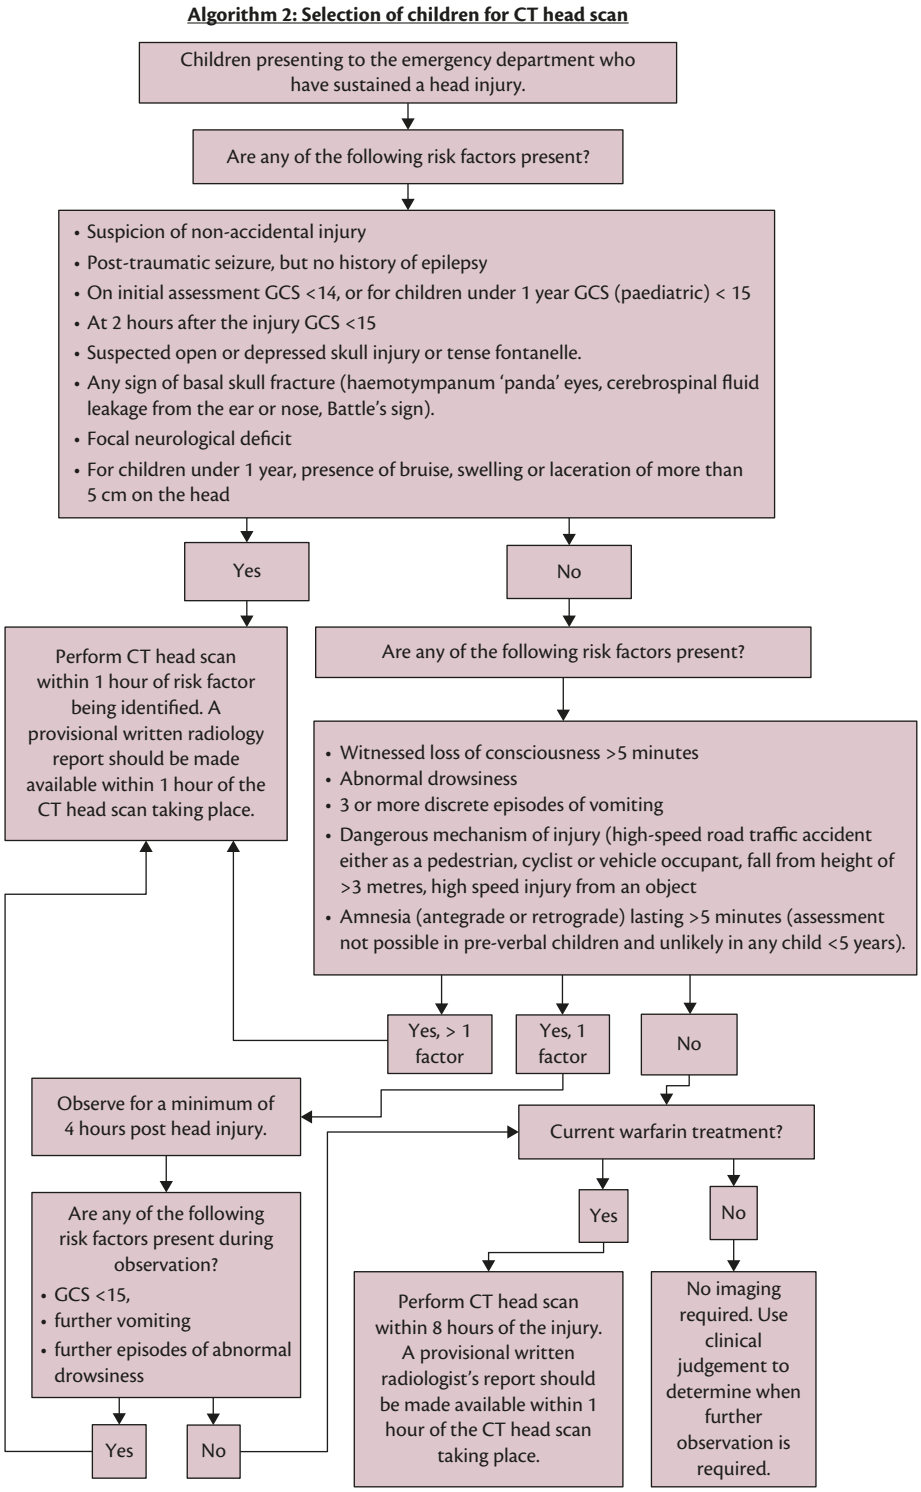
Prognosis is poor where CPP is less than 40 mmHg (highly predictive of mortality), there is bilateral absence of somatosensory evoked potentials (SSEPs) (strongly associated with severe disability and death) or a prolonged period with an ICP above 20 mmHg.

Non-accidental injury

NAI or abusive head trauma is the most common cause of serious or fatal brain injuries in children aged 2 years and younger and can be due to impact or shaking or both. Children diagnosed with NAI are five times more likely to die compared with accidentally head-injured children, yet signs and symptoms are not always obvious, and therefore the diagnosis can be overlooked (Hinds et al., 2015).

Shaking typically results in recent multifocal haemorrhages and/or large chronic subdural haemorrhages extending over both cerebral hemispheres (**Fig. 87.3**). Shaking results in tearing of bridging veins. While the volume of haemorrhage is usually small it is the pattern that distinguishes shaking from impact. There is a strong association between multiple, interhemispheric, convexity, and posterior fossa haemorrhages and NAI.

NICE National Institute for Health and Care Excellence!

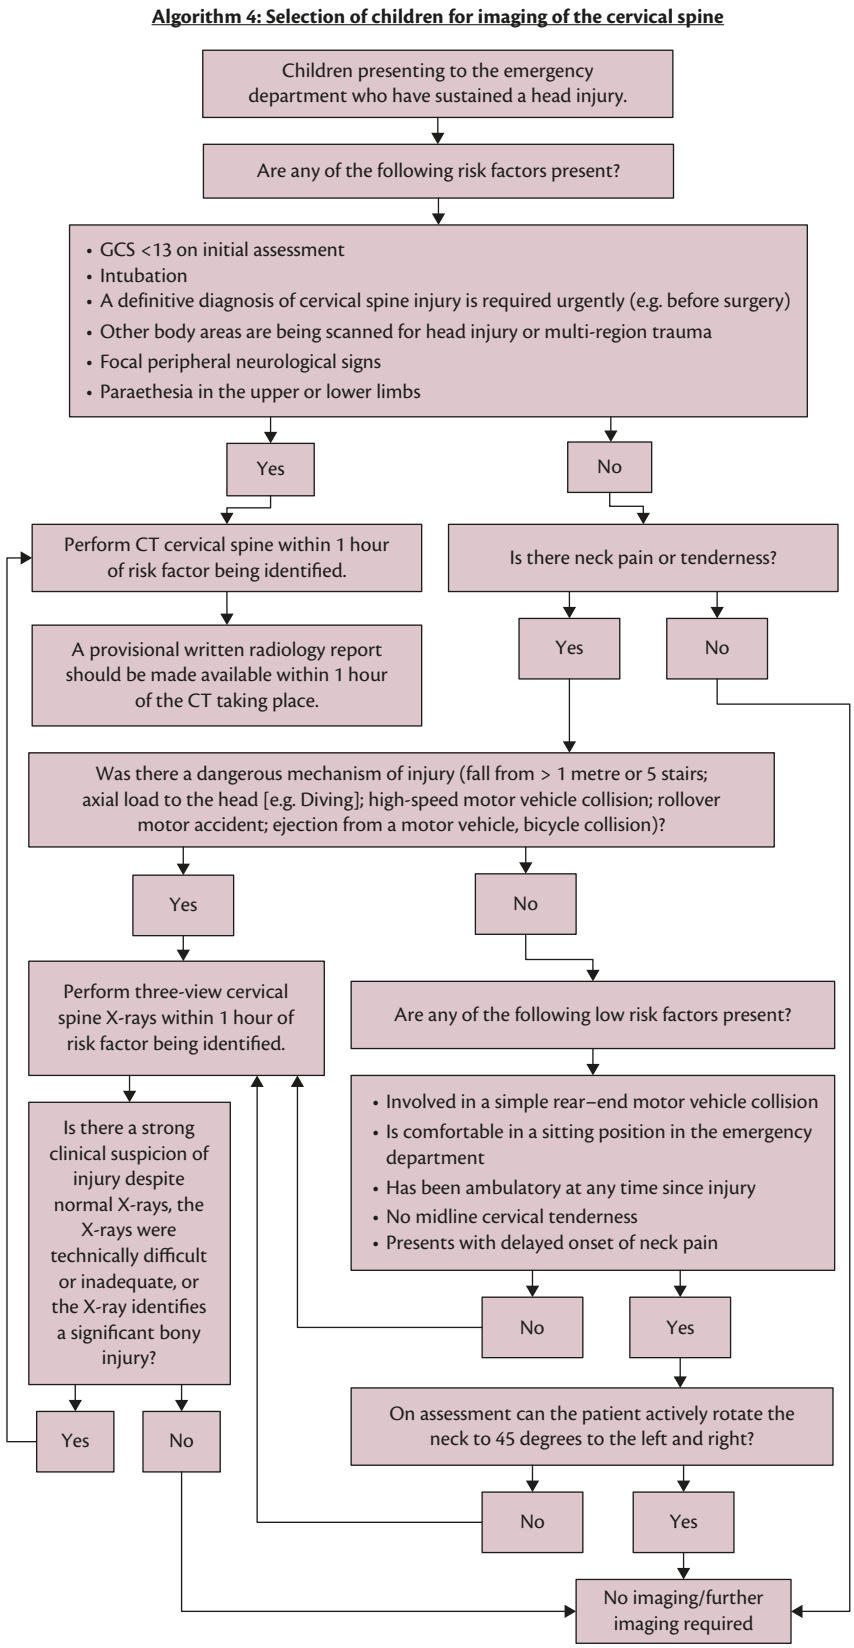


Algorithm 2: Selection of children for CT head scan
Children presenting to the emergency department who have sustained a head injury.
Are any of the following risk factors present?
• Suspicion of non-accidental injury
• Post-traumatic seizure, but no history of epilepsy
• On initial assessment GCS <14, or for children under 1 year GCS (paediatric) < 15
• At 2 hours after the injury GCS <15
• Suspected open or depressed skull injury or tense fontanelle.
• Any sign of basal skull fracture (haemotympanum 'panda' eyes, cerebrospinal fluid leakage from the ear or nose, Battle's sign).
• Focal neurological deficit
• For children under 1 year, presence of bruise, swelling or laceration of more than 5 cm on the head
Yes
No
Perform CT head scan within 1 hour of risk factor being identified. A provisional written radiology report should be made available within 1 hour of the CT head scan taking place.
Are any of the following risk factors present?
• Witnessed loss of consciousness >5 minutes
• Abnormal drowsiness
• 3 or more discrete episodes of vomiting
• Dangerous mechanism of injury (high-speed road traffic accident either as a pedestrian, cyclist or vehicle occupant, fall from height of >3 metres, high speed injury from an object
• Amnesia (antegrade or retrograde) lasting >5 minutes (assessment not possible in pre-verbal children and unlikely in any child <5 years).
Yes, > 1 factor
Yes, 1 factor
No
Observe for a minimum of 4 hours post head injury.
Current warfarin treatment?
Are any of the following risk factors present during observation?
• GCS <15,
• further vomiting
• further episodes of abnormal drowsiness
Yes
No
Yes
No
Perform CT head scan within 8 hours of the injury. A provisional written radiologist's report should be made available within 1 hour of the CT head scan taking place.
No imaging required. Use clinical judgement to determine when further observation is required.

Fig. 87.1 Algorithm published by the National Institute of Clinical Excellence on selection of children for CT head scan.

© National Institute for Health and Care Excellence, 2014. 'Head injury', NICE clinical guideline 176. London: National Clinical Guideline Centre (https://www.guidance.nice.org.uk/CG176).

NICE National Institue for Health and Care Excellance!



Algorithm 4: Selection of children for imaging of the cervical spine
Children presenting to the emergency department who have sustained a head injury.
Are any of the following risk factors present?
• GCS <13 on initial assessment
• Intubation
• A definitive diagnosis of cervical spine injury is required urgently (e.g. before surgery)
• Other body areas are being scanned for head injury or multi-region trauma
• Focal peripheral neurological signs
• Paraethesia in the upper or lower limbs
Yes
No
Perform CT cervical spine within 1 hour of risk factor being identified.
A provisional written radiology report should be made available within 1 hour of the CT taking place.
Is there neck pain or tenderness?
Yes
No
Was there a dangerous mechanism of injury (fall from > 1 metre or 5 stairs; axial load to the head [e.g. Diving]; high-speed motor vehicle collision; rollover motor accident; ejection from a motor vehicle, bicycle collision)?
Yes
No
Perform three-view cervical spine X-rays within 1 hour of risk factor being identified.
Are any of the following low risk factors present?
• Involved in a simple rear–end motor vehicle collision
• Is comfortable in a sitting position in the emergency department
• Has been ambulatory at any time since injury
• No midline cervical tenderness
• Presents with delayed onset of neck pain
Is there a strong clinical suspicion of injury despite normal X-rays, the X-rays were technically difficult or inadequate, or the X-ray identifies a significant bony injury?
No
Yes
On assessment can the patient actively rotate the neck to 45 degrees to the left and right?
Yes
No
No
Yes
No imaging/further imaging required

Fig. 87.2 Algorithm published by the National Institute of Clinical Excellence on selection of children for imaging of the cervical spine.

© National Institute for Health and Care Excellence, 2014. 'Head injury', NICE clinical guideline 176. London: National Clinical Guideline Centre (https://www.guidance.nice.org.uk/CG176).

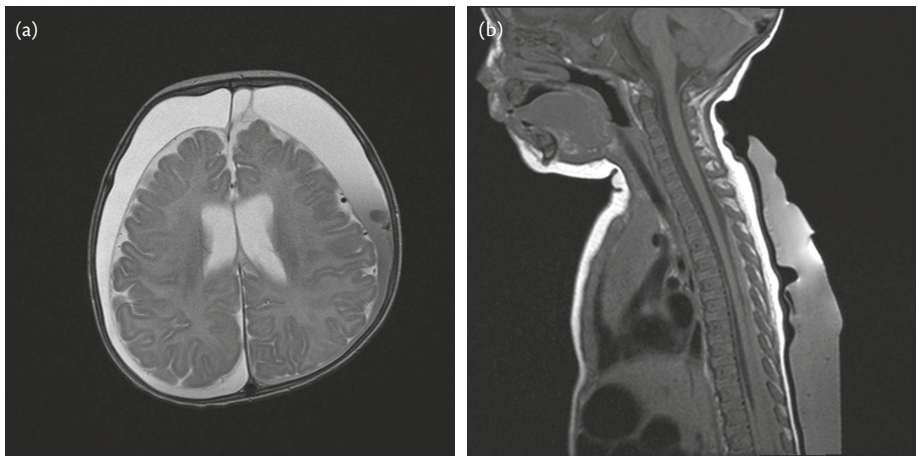


Fig. 87.3 MRI scan showing features of a child consistent with non-accidental injury. (A) shows a bilateral subdural haemorrhage, note the crossing anterior vein and lack of cortical vessels which differentiates this from external hydrocephalus. (B) A spinal subdural haemorrhage.

Subdural haematoma does occur in accidental trauma and other causes of subdural haematoma also need to be considered in this age group including birth trauma where the haematoma usually resolves by 4 weeks of age, blood clotting disorders, or rare metabolic disorders such as glutaric aciduria type I.

The association of subdural haemorrhage(s), retinal haemorrhages, and acute encephalopathy in a previously well baby constitute the so-called triad. In suspected NAI, a full skeletal survey and complete haematological workup is warranted. Neuroimaging is crucial in establishing the diagnosis of NAI as it detects occult injury in 37% of cases. Several imaging patterns are considered to be particularly associated with NAI. The presence of a subdural hematoma, especially in multiple locations, such as the interhemispheric region, over the convexity and in the posterior fossa, is significantly associated with NAI. Although CT is the recommended first-line imaging modality for suspected NAI, early MRI is increasingly used alongside CT because it provides a better estimation of shear injuries, hypoxic-ischaemic insults, and the timing of lesions. (Vázquez et al., 2014)

If NAI is suspected the case should be referred immediately to the appropriate children's safeguarding/child protection team for further investigation. The acute surgical management of suspected NAI should be discussed immediately with the regional paediatric neurosurgical unit. Management of acute encephalopathy in severe cases requires the expertise of paediatric intensive care and paediatric neurology. Management of retinal haemorrhages requires ophthalmological follow-up.

Growing fractures

A growing fracture is a rare post skull fracture phenomenon (Fig. 87.4). In addition to the skull fracture, the underlying adherent dura and arachnoid are torn and widen over time due to the cerebral pulsations and growing brain, resulting in herniation of the cerebrum through the dural and arachnoid tear.

A more rare and severe form of growing fracture is a 'burst fracture', where there is wide diastasis of the fracture and a more significant acute underlying brain injury with damaged cerebral tissue. Management consists of traumatic brain injury ICP management with subsequent surgical repair of the overlying defect.

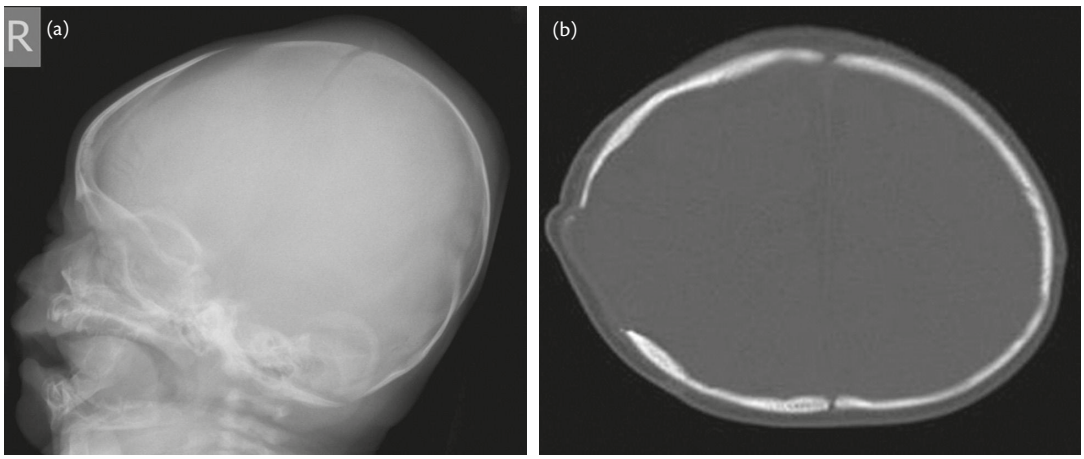

Fig. 87.4 CT scan demonstrating a growing skull fracture on days 1 (A) and 50 (B). Note how the fracture starts as a linear fracture then grows bigger as a result of cerebrospinal fluid (CSF) pulsation.

Half of children affected are under 1 year old and 90% are under 3 years old. Growing fractures usually present as a non-tender scalp swelling, most commonly in the parietal region.

Several factors indicate a potentially poorer outcome including age less than 8 years, female gender, defect less than 7 cm, a defect that crosses over the midline and a delay of more than 8 months in time to repair.

Children with a linear fracture aged less than 3 should be assessed clinically 6 weeks postinjury to look for growing fractures. Treatment of growing fractures involves either a duraplasty or split calvarial duracranioplasty.

Ping pong fractures

A 'ping pong' fracture occurs in young children and neonates. Mechanisms include birth trauma, and accidental and non-accidental injuries.

It occurs following the 'buckling' of the malleable inner table of the calvarium without a formal outer table (cortical) break in continuity. The periosteum remains intact and there is rarely an underlying brain injury (see Fig. 87.5).

The vast majority resolve naturally due to calvarial remodelling from underlying brain growth. In those with neurological deficit or in those deemed cosmetically significant (after approximately 6 months of observation), elevation can be considered.

Spinal injury in children

In trauma, 25–50% of children with a SCI will have an associated head injury. The younger the child, the more likely an upper cervical spine injury is to occur. There are several reasons for this. The integrity and alignment of the spine is maintained mainly by strong ligaments. At the craniocervical junction, several important ligaments connect the flexible craniocervical junction and permit movements between a disproportionately heavy head and a small, only partly ossified upper neck. The ligaments also secure the C1/C2 vertebrae together. Younger children possess greater ligamentous flexibility and the head to neck size ratio is greater. In older children, less flexible, stronger ligaments and heavier neck structure shift the fulcrum to the midcervical spine, where injuries are more likely to occur at C5/C6 as in adults.

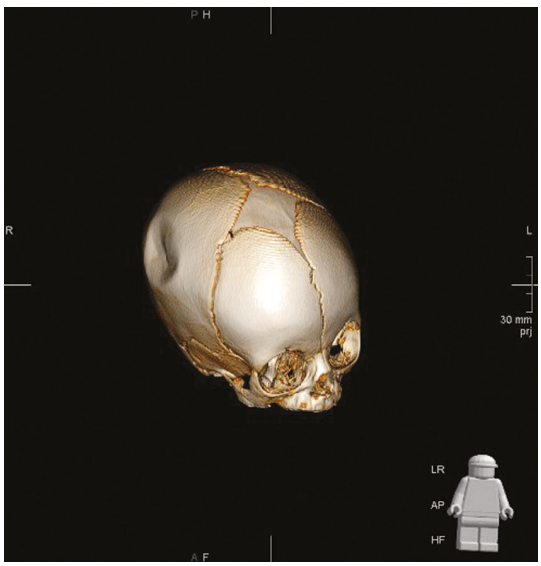

Fig. 87.5 CT scan showing a ping pong fracture. These fractures will usually remodel as the brain grows.

The cartilaginous posterior arch of the C1 ring ossifies by the age of 3 years, while the C2 body ossifies at 6 and the tip of dens at about 12 years. Under 8 years, the midline part of the C1 ring remains weak. C1 ring fractures commonly occur from rotational and compression injuries. Similarly, C2 fractures can occur. Atlantoaxial rotational injuries are very likely due to ligamentous flexibility and easier traumatic disruption at the C1/C2 level. Fracture-dislocations also commonly occur at the C1/C2 level.

The position of the facet joints is horizontal in the very young increasing the risk of horizontal subluxation, and translocation with consequent risk of spinal cord injury. SCIWORA injuries are much more common in the young and mostly occur above C3, they carry a high risk of neurological damage.

Several underlying conditions such as Down's syndrome, the mucopolysaccharidosis (Hurler's, Hurler-Scheie, Hunter's, Morquio-Brailsford, Maroteaux-Lamy), rheumatoid arthritis, and achondroplasia are specifically associated with spinal involvement. The pathology often involves ligamentous laxity (Down's syndrome) and deposition of GAGs (glycosaminoglycans). These may be deposited in the facets and atlantoaxial joints and, in the case of Maroteaux-Lamy, in the dura mater, the posterior longitudinal, and flavum ligaments. In rheumatoid arthritis there are inflammatory changes in the joints and bones. In achondroplasia, an FGFR-3 abnormality causes accelerated ossification leading to craniocervical stenosis and medullary compression. Spinal canal stenosis may occur either segmentally or diffusely over multiple segments with lateral recess impingement.

At any age, these conditions lead to variable spinal canal stenosis, atlantoaxial instability, and deformation mainly cervicothoracic and thoracolumbar kyphotic gibbus and scoliosis. The end point is spinal cord compression which if untreated will progress to myelopathic cord changes. These children are particularly exposed to a greater risk of both skeletal and neurological injury from moderate spinal trauma.

Paediatric developmental anatomy and radiology

The paediatric spine will only reach adult proportions by the age of 10–12 years. Several bones including the arch of C1 and the C2 body and lateral masses will not ossify until the age of 3 years (Munk and Ryan, 2007).

Os odontoideum was previously thought to be congenital but is now considered to be non-union of an odontoid fracture occurring before the age of 6. It can be unstable and flexion/extension X-rays should be performed. Os odontoideum should be distinguished from a persistant ossiculum terminale which is a failure of fusion of the terminal ossification centre in the dens. The ossification centre appears between 3 and 6 years, fusion normally occurs by the age of 12 (Fig. 87.6).

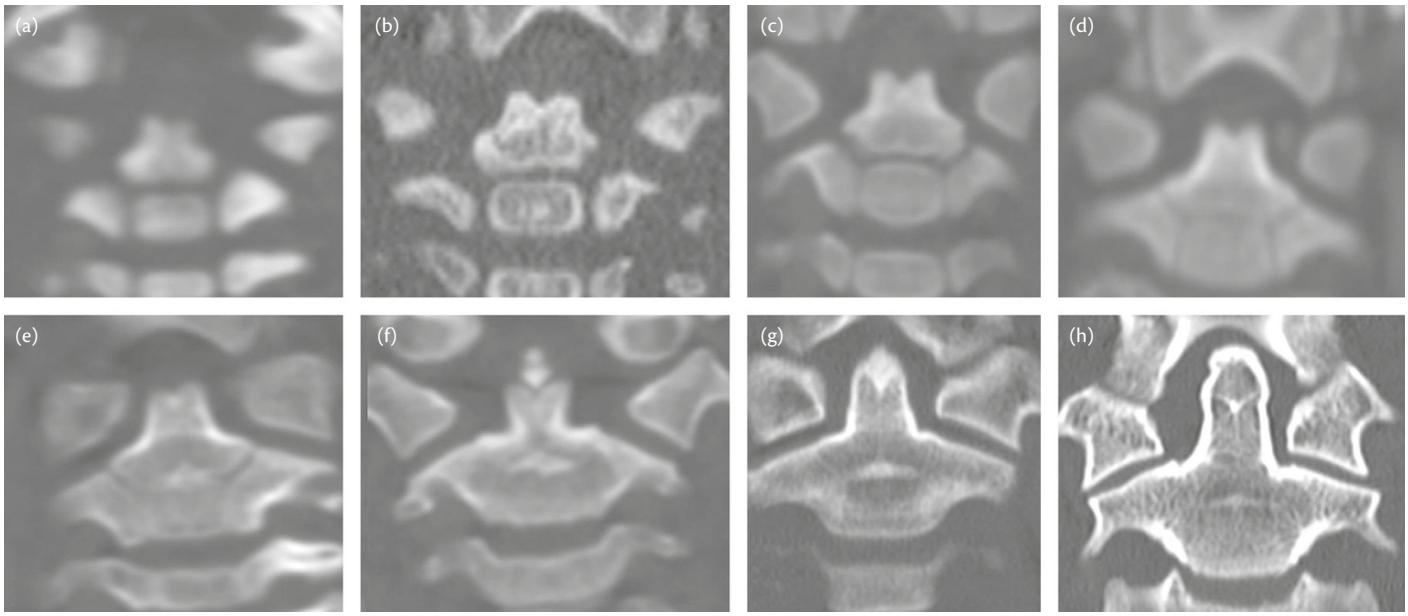

Fig. 87.6 Coronal view of ossification development of the axis. Children are of the following ages: (A) 30 days, (B) 5 months, (C) 1.5 years, (D) 2 years, (E) 3 years, (F) 5 years, (G) 8.5 years, and (H) 14 years.

Under 8 years, both C2 and C3 can show pseudo-subluxation in up to 46% and 14%, respectively. A movement of up to 4 mm or 40% may be a physiological vertebral pseudosubluxation. About one-fifth of children admitted for polytrauma may demonstrate this incidental finding which is due to incomplete ossification, hypermobility, and the fact that facets are horizontal in young children. Pseudosubluxation will reduce on extension and there should be no soft tissue swelling.

In the cervical spine neutral or dynamic views allow evaluation of the atlantodental interval (normally less than 5 mm) indicating transverse and alar ligamentous injury and horizontal instability. Trapezoidal vertebral shape, scoliosis, or offset spinous processes raise suspicion of acute injury somewhere along the spine.

Birth injuries

These may occur following mechanical repositioning of the fetus, or assisted delivery. The upper cervical and cervicothoracic junction are the most affected. These injuries are underdiagnosed mainly because of the lack of radiographic findings at birth, but the mortality for birth-related SCI is high and survivors may have a poor prognosis. Improved prenatal monitoring and obstetric techniques have helped reduce the incidence of these injuries.

Infant brachial plexus injury results from excessive force during delivery. Risk factors are difficult deliveries with the use of forceps or vacuum extraction or a breech delivery, fetal macrosomia, infant shoulder dystocia, and maternal diabetes/obesity. In brachial plexus injuries, conservative treatment with physiotherapy is recommended for the first three months as most injuries heal spontaneously. Subsequently a nerve transfer or grafting surgery may be undertaken.

Atlantoaxial injuries

Atlanto-occipital (C0/C1) and atlantoaxial (C1/C2) dislocation may occur in young children as a result of the relatively large head size in comparison to the body. These injuries are frequently fatal. Treatment in survivors requires craniocervical or atlantoaxial fusion. There is widening of the atlanto-occipital joint by more than 5 mm or the C1/C2 interspinous distance by more than 10–12 mm. These injuries are often the result of a severe RTA and occur five times more often in children than adults. Rupture of the tectorial membrane and alar ligaments in the presence of small occipital condyles and horizontally oriented atlanto-occipital joints allows for the dislocation to occur.

MRI scanning is helpful to confirm the ligament injury. Ligament injuries do not normally heal well with conservative treatment and surgery is likely to be required for more severe cases.

Atlantoaxial rotatory subluxation

Fixed rotation of C1 on C2 may occur. This is caused by subluxation or facet dislocation and it is a common cause of childhood torticollis which presents with neck pain and a fixed tilted 'wry' neck held in the cock robin position. There is a reduced range of motion, the contra-lateral sternocleidomastoid is taut, and the child may have headaches or difficulty with chewing. The diagnosis is often delayed, with average presentation occurring around 5 weeks after onset.

It may be post-traumatic but in children is also seen following retropharyngeal infectious oedema secondary to an upper respiratory tract infection leading to ligamentous laxity, known as Grisel's syndrome. Other predisposing conditions include Down's syndrome, rheumatoid arthritis, posterior fossa tumours, and congenital anomalies.

If the transverse ligament is intact, spinal canal stenosis can only occur with severe rotation and facet dislocation. However, if the transverse ligament is ruptured, the ADI (atlantodental interval) or anterolisthesis will be more than 5 mm. Spinal canal stenosis occurs with only 45 degrees rotation and vertebral arteries are at risk.

A CT is obtained with the head in a neutral position and then in maximal rotation to right and left. In rotatory subluxation the subluxation of C1 on C2 does not change. An MRI should be performed if neurological symptoms or deficits occur to rule out the differential diagnosis of a brainstem lesion.

Fielding's classification is commonly used (see Table 87.2).

Many patients probably reduce spontaneously before seeking medical attention. In subluxations present for less than 1 week, a soft collar, anti-inflammatory medications, and exercise programme can be used. If subluxation persists longer, consider manipulation under anaesthetic, muscle relaxant, and a hard collar (head halter traction and bracing are alternative choices for older children). Occasionally halo traction or C1–C2 fusion may be required.

Lumbar spine injuries in children

Depending on which combination of columns are injured, fractures are described as compression, burst, seat-belt, or fracture-dislocation injuries.

Wedge compression fractures are the most frequently seen fractures, occurring as a result of an axial compression load to the anterior vertebra in flexion. This is a stable injury without spinal canal compromise or spinal cord injury. Kyphotic angulation can occur because there is reduction in anterior vertebral height.

Hinging or seat-belt fractures are caused by extreme bending in sudden acceleration deceleration injuries. Chance fractures are commonly reported in children. The mechanics are associated with seat belts and therefore are often associated with abdominal injuries.

Burst fractures occur from axial load without flexion, and affect the anterior and middle columns. Around 15–20% of all major vertebral body fractures are of this type. There is disruption of the posterior vertebral wall, with fragments that break into the spinal canal and there may be a spinal cord injury.

Three-column injuries come from a shearing injury with sudden severe flexion and rotation. These are inherently unstable and characterized by failure of all three columns. They account for approximately 20% of all spinal injuries and are associated with the highest likelihood of SCI. Approximately 75% of patients with fracture-dislocation injuries have some neurological deficit and 50% of these have complete SCIs.

Table 87.2 Fielding Classification of rotatory atlantoaxial subluxation

Type I	Unilateral facet subluxation with intact transverse ligament	Common Mostly benign
Type II	Unilateral facet subluxation with 3–5 mm of anterior displacement. Injured transverse ligament	
Type III	Bilateral anterior facet displacement of over 5 mm. Both lateral masses are displaced	Rare Higher risk of neurologic involvement
Type IV	Posterior displacement of C1	Rare Higher risk of neurologic involvement

Reproduced with permission from JW Fielding and RJ Hawkins, Atlanto-axial rotatory fixation. (Fixed rotatory subluxation of the atlanto-axial joint), *Journal of Bone & Joint Surgery*, Volume 59, Issue 1, pp. 37–44, Copyright © 1977 Wolters Kluwer Health, Inc.

Spinal cord injury without overt radiographic abnormality (SCIWORA)

SCIWORA occurs in younger children with definite clinical neurological deficits and negative X-rays and CT scans. The MRI scan, however, is likely to show an abnormality in the cord, disc, or ligaments. The cord may be mildly to severely injured, and it is thought to occur because of the more elastic spinal column and ligamentous laxity in children, causing a sudden displacement of the spinal column back and forth, injuring the spinal cord without apparent dislocation. The neurological deficits are due to cord or vascular injury during hyperextension/hyperflexion or translocation of the spinal segment.

MRI should be performed as a haematoma compressing the cord, or ligamentous disruption and instability lead to secondary cord insults and are treatable by decompression or stabilization, respectively. These injuries are rarely identified on plain radiography or CT scanning.

Children with SCIWORA are at increased risk of recurrent and more severe injuries if left untreated. External immobilization is recommended for 6–8 weeks and if unstable consider surgical fixation.

Management of spinal cord injury

Treatment of traumatic SCI starts at the site with immediate resuscitation and transport with spine immobilization. PICU care includes improving spinal cord perfusion by maintaining adequate blood pressure with inotropes and if required supportive ventilation.

Spinal injuries in children require adequate imaging including CT and MRI for prompt and clear identification of all injuries often not seen on radiography or even CT scans. Identification of ligamentous injuries, fractures with malalignment or deformation, compressive lesions, instability, and SCI is essential. Dynamic flexion/extension views may be required.

Surgical evacuation of a compressive haematoma should be treated as urgent to avoid secondary spinal cord injury. Deformity with compression of the spinal cord may require placing a child in traction and then externally fixing in a halo-brace system once corrected. Later on, a surgical correction and fixation may be required. Cervical spine fractures without spinal cord compression can usually be treated with a halo device. It is crucial that in cases of fractures treated by immobilization, that long-term follow-up is performed as progressive deformity or instability over time does occur.

Rehabilitation of spinal cord injury

This is generally similar to adult care standards. The ASIA impairment scale is used to define and describe the extent and severity of the spinal cord injury and help determine future rehabilitation and

recovery needs (American Spinal Injury Association, 2002). It is ideally completed within 72 hours of the initial injury. Sensory and motor evaluation in children requires careful testing and re-testing. Scoliosis following SCI in children is common especially when the neurological insult occurs at a young age.

Intensive rehabilitation maximizes the potential for recovery of function or ability to function with existing deficits. Spinal rehabilitation is a multidisciplinary effort and the spinal unit should be involved at the outset with a referral within 48 hours.

Controversies in paediatric trauma

There are studies looking at the neuroprotective nature of hypothermia in children. Hypothermia effectively reduces intracranial pressure and metabolic demand but there are risks of cardiac arrhythmias and coagulation deficits. Early studies showed no increase in adverse events and a larger randomized controlled study was undertaken. This trial published in 2008 shows moderate hypothermia therapy (32–33°C), initiated within 8 hours after the injury and maintained for 24 hours, did not improve the functional outcome at 6 months or functional and neuropsychological outcomes at 3 and 12 months, length of stay in the ICU or hospital, and adverse events. (Hutchison et al., 2008). There are four other studies in children that have shown no benefit. There are 14 studies in adults with variable results. Hypothermia is now little used but still sometimes raised as a potential subject for a large clinical trial.

Paediatric brain tumours

Jonathan Roth and Shlomi Constantini

Introduction and epidemiology

Paediatric brain tumours (PBT) are a unique entity, in children and in the overall general brain tumour population. Malignant paediatric brain tumours (MPBT) are second only to acute lymphatic leukaemia (ALL) in their incidence and during recent years, their incidence is continuing to increase. Around 30% of paediatric deaths due to cancer are caused by MPBT, three times that caused by ALL. The incidence of PBT is $4.5/10^5$ (Ostrom et al., 2015). This is significantly less than the incidence of adult brain tumours, which is $16.5/10^5$. The incidence of PBT is slightly more common in males (M:F ratio 4.5:4). White children have nearly double the incidence of black children. The reason for this discrepancy, which is maintained in other cancers too, is not known. About 50% of PBT are malignant. Age has a major impact on incidence, histological type, and outcome of PBT. Younger children (especially younger than 5 years old) have an incidence of $3.5–4/10^5$ with a 5-year survival of about 50%. Older children (10–20 years old) have an incidence of $2–2.5/10^5$ with a 5-year survival of about 75%. The 5-year survival for all paediatric patients is about 65%. This rate decreases continuously with age, down to about 23% among patients 45–54 years old.

Treatment for the paediatric population has a few goals: firstly, curing or controlling the disease and increasing long-term survival; secondly, preventing long-term complications from the various diagnostic and treatment modalities needed to treat the primary disease; and thirdly, minimizing the psychosocial impacts of the diagnosis as well as treatments on the child and the family.

Common paediatric brain tumours

Paediatric brain tumours differ from those of the adult population in several aspects, including histological (and genetic basis of the tumours), location, treatment options, and prognosis.

As opposed to adults where two-thirds of primary brain tumours are located in the cerebrum, only a quarter of paediatric tumours are located there (**Tables 88.1 and 88.2**). Nearly 30% of PBT are located in the posterior fossa (including the brainstem and cerebellum), as opposed to 7% of primary brain tumours in adults. Children have a higher rate of midline tumours (including the hypothalamic, optic pathways, pineal and pituitary regions, and the ventricular system) as opposed to adults (Ostrom et al., 2015).

Histology differs too between both populations. Certain tumours are considered 'childhood' histologies, such as pilocytic astrocytomas, medulloblastomas, and germ cell tumours. While other subtypes such as glioblastomas and meningiomas, are rare among children (Ostrom et al., 2015).

Low-grade gliomas

Low-grade gliomas in children account for about 40% of PBT, the most common subtype being WHO I pilocytic astrocytoma (PA), accounting for about half of LGG in children. Other LGG subtypes that occur more commonly in children include dysembryonal neuroectodermal tumour (DNET, WHO I), ganglioglioma (WHO I), pilomyxoid astrocytoma (WHO II), pleomorphic xanthoastrocytoma (PXA, WHO II). Diffuse astrocytoma (grade II) and oligodendrogliomas (grade II) occur too in children, but to a lesser extent compared to the adult population. These tumour subtypes are subclassified in the 2016 WHO CNS tumour classification (Louis et al., 2016).

LGG may occur at any location, although certain locations have a higher prevalence, including cerebellum, brainstem, optic pathways, hypothalamus, and temporal lobe.

Cytogenetic studies have revealed a normal karyotype in the majority of pilocytic astrocytomas examined (Sanoudou et al., 2000). Where abnormal profiles have been observed, no consistent karyotype abnormalities have been identified.

Individuals with neurofibromatosis type 1 (NF1) have an increased propensity to develop pilocytic astrocytomas, especially of the optic/hypothalamic region. As sporadic (non-NF1) pilocytic astrocytomas occasionally show loss of heterozygosity on chromosome 17q (the location of the *NF1* tumour suppressor gene), one would predict that mutations of the *NF1* gene with consequent loss of expression would be found in sporadic pilocytic astrocytomas. In fact, this appears not to be the case. In actuality, the expression of the *NF1* tumour suppressor gene in sporadic pilocytic astrocytomas is often up-regulated, perhaps as a reactive response to excessive cellular proliferation. This is in contrast to pilocytic astrocytomas arising in *NF1* patients, where loss of *NF1* expression is an obligatory

Table 88.1 Distribution of primary brain and CNS tumours by location according to age

<19 years old	Adults
Cerebellum 16%	3%
Brain stem 12%	4.3%
Ventricles 5.6%	1.8%
Cerebrum 24%	65%
Pineal 3%	–
Pituitary 8%	7%
Cranial nerves 4.6%	1%
Spinal cord 5.6%	4.2%

Data from Ostrom, Q.T., De Blank, P.M., Kruchko, C., Petersen, C.M., Liao, P., Finlay, J.L., Stearns, D.S., Wolff, J.E., Wolinsky, Y., Letterio, J.J., & Barnholtz-Sloan, J.S., Alex's Lemonade Stand Foundation Infant and Childhood Primary Brain and Central Nervous System Tumors Diagnosed in the United States in 2007–2011, *Neuro-Oncology*, Volume 16, Issue s_10, pp. x1–x36, Copyright © 2014 Oxford University Press.

finding. The precise origin of the differing contribution of the *NF1* gene product in the setting of *NF1* versus non-*NF1* pilocytic astrocytomas has yet to be elucidated.

Compared to adult LGG, mutations in tumour suppression gene *TP53*, and metabolic genes *IDH1* and *IDH2*, are exceedingly rare in childhood LGG (Chalil and Ramaswamy, 2015).

Advanced molecular analysis has shown that the most common chromosomal abnormality in PA is a gain of chromosomal region 7q34, containing the BRAF locus. This involves duplication of the BRAF oncogene, followed by insertion of one of several fusion targets. This activates the MAPK pathway, leading to tumourigenesis (Chalil and Ramaswamy, 2015).

BRAF V600E mutations are found in a small proportion of LGG, activating and causing a deregulation of the MAPK pathway. Over recent years, the MAPK pathway has become a target for chemotherapy in tumours harbouring such BRAF mutations or duplications.

Cerebellar pilocytic astrocytoma

Posterior fossa pilocytic astrocytomas are considered one of the 'classic' PBT. Often presenting with gait disturbances and increased intracranial pressure (ICP) symptoms secondary to hydrocephalus, these tumours are typically located in the cerebellar hemisphere; however, midline—vermian or tumour protruding to the fourth ventricle have been described too. These tumours often have a solid component, many times with cystic components too. The cysts may be located within the tumour, or adjacent to it, and its walls may undergo contrast enhancement on MRI.

Cerebellar pilocytic astrocytomas have a differential diagnosis with other tumours, including hemangioblastomas which may have an enhancing nodule accompanied by a cyst. It is important to acknowledge that PA may have solid components that do not undergo any enhancement, and thus other MRI modalities such as fluid attenuated inversion recovery (FLAIR) may assist defining the tumour outline. Interestingly, paediatric PA may appear like adult high-grade gliomas, composing of solid-cystic components with non-homogenous enhancements. However, HGG are rare in the paediatric population, and these are rarely diagnosed in the cerebellum.

Treatment of cerebellar PA consists of maximally safe resection. This is usually achieved using standard microsurgical techniques. Often, these tumours abate the brainstem or cerebellar peduncle; thus, judicious judgement is needed to decide when to finalize the resection.

In children, especially infants, lateral cerebellar hemispheric tissue may generally be resected with little or no long-term neurological sequala. Thus, a safe and convenient surgical corridor may be created obviating the need for significant cerebellar retraction.

One of the questions a surgeon is often faced with is the need to resect a cyst's capsule. Often the capsule undergoes contrast enhancement on MRI, thus possibly suggesting it being part of the tumour. However, we have previously shown by performing local biopsies, that if the capsule is inspected during surgery and seems transparent, with no tumoural lumps, it need not be resected (Beni-Adani et al., 2000).

The long-term recurrence rate following a gross total resection (as proved by MRI) is thought to be low. However, a recent paper showed that even in the presence of surgeon's estimation of GTR, and a clean MRI, the 5-year event free survival (no recurrence) is 95% (most occurring during first 3 years) (Dodgshun et al., 2016). Another recent study found a 19% recurrence rate following GTR of cerebellar PA over a 10-year follow-up (Kim et al., 2014). Thus, long-term follow-up even after GTR is mandatory.

Table 88.2 Distribution of primary brain and CNS tumours by histology according to age. The most common pathologies are in bold

0–14 years old	15–19 years old	Adults
Pilocytic astrocytoma **20.9%**	**14 %**	Meningioma **30.1%**
Embryonal (including medulloblastoma) **16.8%**	6.7%	Glioblastoma **20.3%**
Glioblastoma 2.8%	3.2%	Nerve sheath 8%
Other astrocytomas **10.5%**	**10.4%**	Pituitary 6.3%
Ependymoma 7%	4.6%	Astrocytoma (grades 2–3) 9.8%
Germ cell tumours 3.9%	6.8%	Oligodendroglioma 3.7%
Craniopharyngioma 3.1%	2.7%	Lymphoma 3.1%
Pituitary 0.8%	**10.1%**	Ependymoma 2.3%
Others 32%	36%	Craniopharyngioma 0.7%
		Others 14%

Brainstem tumours

Brainstem gliomas (BSG) in children include a diverse group of tumours with different presenting symptoms and tumour configurations that lead to a plethora of biological behaviours and variable prognoses. BSG represent 10–20% of all paediatric brain tumours, and about 20–30% of infratentorial tumours. BSG are diagnosed at all ages. However, they are rarely diagnosed before the age of 5 years, and their occurrence peaks at around the age of 10 years. Males and females are more-or-less equally affected.

As opposed to cerebellar and many supratentorial tumours, BSG involves super-eloquent neural tissue, and thus were previously considered inoperable. However, as has been showed by Epstein and others, in selected subgroups of tumours, and with the integration

of intraoperative mapping and monitoring, resection is feasible with reasonable neurological and oncological outcome (Constantini and Epstein, 1996). With the addition of gentle chemotherapy and modern radiation techniques, decision-making on the combination of treatment options has become more complex. Currently, there is no unified approach for BSG. Treatment is dictated by tumour location, configuration, and biological behaviour.

BSG include all WHO grades I-IV astrocytomas. Grade I tumours (also called pilocytic astrocytomas) usually present as discrete lesions, often with a cystic component; however, they may present as dorsally exophytic tectal or medullary (and cervicomedullary) tumours. They usually enhance following gadolinium, and may be associated with significant oedema (for instance, in the cervical spine). Often, the tumour includes non-enhancing components too.

WHO grade II tumours (diffuse low-grade astrocytomas) may present in any location along the brainstem. Their biological behaviour is very diverse. Tectal and exophytic tumours usually have a very indolent course. On the other hand, diffuse pontine gliomas (DPG) may also have the histological appearance of WHO II but behave aggressively. WHO grade II tumours usually do not enhance, are hypointense on T1, and hyperintense on T2 and FLAIR.

WHO grades III and IV tumours (anaplastic astrocytomas and glioblastoma multiforme) may arise in any location, more commonly in the pons (as a DPG). They are often associated with ill-defined enhancement (grade III) or a necrotic, ring-enhancing component (grade IV).

Other glial pathologies may rarely arise in the brainstem, including gangliogliomas, oligodendrogliomas, and pilomyxoid astrocytomas.

Ependymomas

Ependymomas are the third most common tumour among children, and are particularly frequent in the very young. Ependymomas are usually located at the fourth ventricle, sometimes emerging through the foramina of Luschka or Megandie and encompassing the brainstem, although they may be located at other locations.

The standard treatment of ependymomas includes gross total resection, even at the expense of the need for a tracheostomy or a gastrostomy to overcome lower brainstem injury when invaded by the tumour.

In posterior fossa ependymomas it is accepted to follow the resection with radiation therapy to the tumour bed. However, the need for radiation following complete resection of ependymomas remains controversial especially in supratentorial cases, but also in infratentorial cases (Ailon et al., 2015). The role of chemotherapy in the treatment of ependymomas remains unclear, so radiation is recommended for children even at ages below 3 years of age (Purdy et al., 2014).

Atypical teratoid rhabdoid tumour (ATRT)

ATRT are aggressive CNS tumours, often affecting infants and young children, and usually located in the posterior fossa. Prognosis is generally poor with a median survival of less than 1 year. ATRT resembles medulloblastoma, and was not recognized until the 1980s. ATRT demonstrates deletion of the long arm of chromosome 22q11.2. Further molecular studies have led to identification of the *INI1/hSNF5* tumour suppressor gene at this location. A somatic mutation in this gene predisposes children to develop ATRT. Some children with ATRT are born with heterozygous germline mutations of the *hSNF5* gene, suggesting that these children were predisposed to develop ATRT (Taylor et al., 2000). In most cases, however, these germline mutations arise *de novo*.

Medulloblastoma

Medulloblastomas are perhaps the hallmark of molecular subtyping of PBT. Until a few years ago children with posterior fossa medulloblastomas (PFMB) were dichotomized into two subgroups—average and high risk, according to age, extent of tumour residual, and metastasis. This dictated treatment algorithms and prognosis. However, over recent years PFMB have been subclassified into four subgroups based on molecular profile, each with a demographic, clinical, molecular, and prognostic pattern (Taylor et al., 2012). These groups include the WNT, SHH, and groups 3 and 4. Surgical nuances (such as brainstem infiltration), radiological (such as magnetic resonance spectroscopy (MRS)) and treatment implications differ between the various subgroups (Northcott et al., 2012). These PFMB subgroups have been implemented into the 2016 WHO CNS tumour classifications (Louis et al., 2016).

As it is anticipated that genetic tumour markers will increasingly inform the selection of adjuvant therapy for the individual patient, it is crucial to collect tumour tissue samples for genetic analysis. In addition, as it is anticipated that genetic research will continue to evolve, there is a need for multicentre cooperation. Tumour banks are being developed for ongoing and future genetic research.

Optic pathway glioma

Optic pathway gliomas (OPG) are low-grade glial tumours that originate from any location along the optic system, such as the optic nerves, chiasm, tracts, or rarely the radiation. OPG are rather rare, representing about 5% of PBT, most of which present during their first decade of life. Many OPG are associated with neurofibromatosis type I (NF1), however, about 40% are non-NF-related (Shofty et al., 2015). Pathology of OPG is usually pilocytic astrocytoma, although pilomyxoid astrocytoma is being increasingly diagnosed, especially among infants.

Much about OPG remains controversial, including classification, diagnosis, need for biopsy, indications for surgery and surgical goals, and the role and timing of chemotherapy and radiation. Thus, in the following paragraphs we will shortly overview this entity, but by no means do we intend to try and solve the many controversies associated with it.

OPG classification is generally guided by anatomical involvement; however, currently there is no good correlation between the various classification systems and the natural history of tumour progression, or to clinical aspects (especially visual prognosis).

Presenting symptoms may relate to visual function from tumour involvement or compression of the visual pathways; be related to hydrocephalus caused by extensive third ventricle with obstruction of cerebrospinal fluid (CSF) pathways; be secondary to diencephalic

compression or involvement leading to diencephalic syndrome (cachexia, microcephalus, and visual decline); or be caused by various endocrinopathies from hypothalamic—pituitary axis disturbances. Especially during infancy, visual function is difficult to accurately evaluate, posing great difficulties on clinical evaluation.

Diagnosis of OPG is often based on radiological appearance with no need for a biopsy. Optic nerve thickening, especially when also enhancing, with or without chiasmatic involvement are diagnostic. When associated with NF1, chiasmatic—hypothalamic tumours are diagnostic for OPG. Despite the importance of MRI for diagnosis of OPG, atypical cases—such as non-NF-related lesions in elder children, with no clear optic nerve origin, or with no chiasmatic swelling—should be biopsied. The biopsy technique will vary according to anatomical considerations—subfrontal for chiasmatic exposure, endoscopic for lesions involving the third ventricle causing hydrocephalus, or stereotactic biopsies. The role of biopsy is both to establish the pathology, as well as to define molecular alterations such as BRAF-KIAA 1549 fusion which have both a prognostic as well as therapeutic implication (Shofty et al., 2015).

The natural history of OPG is unpredictable. Some remain stable over years, while others grow. Often, visual decline may appear with no clear change in tumour morphology. Generally, NF-related OPG have a more indolent course compared to sporadic cases.

Treatment of OPG requires a multidisciplinary team approach, taking into account clinical (with emphasis on ophthalmological evaluation), radiological dynamics, surgical considerations, as well as oncological aspects.

Generally, stable tumours associated with stable visual exam are usually followed. However, large tumours with an extensive exophytic component extending to the subfrontal region, or those extending upward to the third ventricle causing hydrocephalus or upper brainstem compression are treated surgically. Approaches to these tumours may include a frontotemporal/subfrontal approach, or various interhemispheric/transventricular approaches. The surgical goal in never complete resection, but rather subtotal removal of the exophytic component and establishment of CSF pathways. Intraoperative imaging has been applied to assist in decision-making regarding extent of resection (Millward et al., 2015).

Ventriculoperitoneal shunts in the context of OPG have been associated with ascites (Gil et al., 2001). The reason is unclear, but shunts may need to be diverted to the atrium.

Chemotherapy is the primary treatment for most OPG. Various protocols have been advised, most starting with vincristine–carboplatin. Despite the vast use of chemotherapy for OPG, long-term visual outcome remains grim (Shofty et al., 2011). Radiation has been applied with various success rates; however, it is associated with vasculopathy (moyamoya), endocrinopathy, and secondary malignancies.

Outcome of OPG is generally favourable with about 85–90% 10-year survival. Thus, preservation of vision is the main goal treating OPG. As stated, and although debatable, the long-term visual outcome remains grim.

Environmental hazards

Infectious agents, especially certain viruses, have been associated with increased risk for certain cancers. Human polyomavirus has been associated with an increased brain tumour risk. Protein transfer from the virus to surrounding cells and secondary dysregulation of cell proliferation factors has been suggested. This may be due either to inactivation of tumour suppressor genes or to upregulating cell proliferation. Weggen et al. have found evidence of several human polyomavirus sequences in human medulloblastomas, meningiomas, and ependymomas. Currently there are no clinical implications for these findings.

Radiation has been associated with an increased risk of brain tumours. Head irradiation for treatment of children with tinea capitis has been shown to be a major risk factor for future benign and malignant tumours. This increased risk has been shown to be even higher among children with neurofibromatosis. Data suggests that even low dose radiation (such as in computed tomography (CT) scans) may induce secondary malignancies, and thus should be as low as possible. The oncogenic mechanism of radiation is to induce genetic changes, either downregulating tumour suppressor genes or upregulating oncogenic genes.

Cell phone exposure has been the focus of various epidemiological studies over the last few years. To date, no clear evidence exists to support, or disprove, the potential risk imposed by cell phones when used by children, but excessive use is discouraged. In adults, the current literature suggests that exposure to the low dose radiation emitted by cell phones does not pose additional risk for developing brain tumours.

An interesting seasonal variation in the incidence of paediatric medulloblastoma has been reported. Children born during autumn (especially during October), had an increased risk for medulloblastomas. Potential causes for this seasonal association may be related to higher levels of community infections during pregnancy and early childhood, or seasonal variation in exposure to various chemicals. However, no clear pathophysiological mechanism has been established.

Diagnosis, investigation, and preoperative considerations

History and examination

The midline location of many paediatric brain tumours results in a paucity of focal neurological signs and delay in diagnosis until the lesion has reached a significant size. Manifestations of paediatric brain tumours may be related to elevated intracranial pressure (secondary to the tumour mass or to secondary hydrocephalus), focal neurological signs, epilepsy, cognitive, and behavioural disturbances, and/or endocrine and growth disturbance. A meta-analysis reviewed childhood CNS tumour presentation (Wilne et al., 2007). Headache, nausea, and vomiting were the most common presenting symptoms, however, appeared only in 30–40% of patients (**Table 88.3**). Presenting symptoms were strongly correlated to the tumour location (**Box 88.1**).

A common complaint among children is headache. Among Swedish school children, 40% experienced a headache by the age of 7 years old, and 75% by the age of 15 years old. Approximately 20% of children in the United States have chronic headaches. Although most cases are due to benign reasons, some may be the presenting symptom of brain tumours. It is important, however,

Table 88.3 Presenting symptoms and signs of paediatric brain tumours

Among 3702 children <18 years old	Among 232 children <4 years old
• Headache (33%) • Nausea and vomiting (32%) • Abnormal gait or coordination (27%) • Papilloedema (13%) • Seizures (13%) • Unspecified symptoms of raised intracranial pressure (10%) • Squint (7%) • Changes in behaviour or school performance (7%) • Macrocephaly (7%) • Cranial nerve palsies (7%) • Lethargy (6%) • Abnormal eye movements (nystagmus, Parinaud syndrome; 6%) • Hemiplegia (6%) • Weight loss (5%) • Focal motor weakness (5%) • Unspecified visual or eye abnormalities (5%) • Altered level of consciousness (5%)	• Macrocephaly (41%) • Nausea and vomiting (30%) • Irritability (24%) • Lethargy (21%) • Abnormal gait and coordination (19%) • Weight loss (14%) • Clinically apparent hydrocephalus (bulging fontanelle, splayed sutures; 13%) • Seizures (10%) • Headache (10%) • Papilloedema (10%) • Unspecified focal signs (10%) • Unspecified symptoms of elevated intracranial pressure (9%) • Focal motor weakness (7%) • Head tilt (7%) • Decreased level of consciousness (7%) • Squint (6%) • Abnormal eye movements (6%) • Developmental delay (5%) • Hemiplegia (5%)

to recognize that not all brain tumours present with headaches, especially in the younger age groups. In one study, 18% of children younger than 5 years old, 52% between 6 and 10 years old, and 68% between 11 and 20 years old with brain tumours presented with headaches. In another study, 62% of children with brain tumours presented with headaches, and more than 50% had at least three associated symptoms, such as nausea, vomiting, visual effects, problems walking, weakness, or changes in personality, school performance, or speech. In our series of PBT, while 40% presented with headaches, only 3% had headaches alone as the sole presenting symptom.

Box 88.1 Presenting symptoms and signs according to tumour location

- Supratentorial tumours:
  - Unspecified symptoms of raised ICP (47%)
  - Seizure (38%)
  - Papilloedema (21%)
- Posterior fossa tumours:
  - Nausea or vomiting (75%)
  - Headaches (67%)
  - Abnormal gait or coordination (60%)
  - Papilloedema (34%)
- Brain stem tumours:
  - Abnormal gait or coordination (78%)
  - Cranial nerve deficits (52%)
  - Pyramidal signs (33%)
  - Headaches (23%)
  - Squint (19%)
- Centrally located tumours (area of third ventricle):
  - Headaches (49%)
  - Abnormal eye movements (20%)
  - Nausea and vomiting (20%)
  - papilloedema (also 20%? Not clear in text)

Reprinted from *The Lancet Oncology*, Volume 8, issue 8, Sophie Wilne, Jacqueline Collier, Colin Kennedy, Karin Koller, Richard Grundy, David Walker, Presentation of childhood CNS tumours: a systematic review and meta-analysis, pp. 685–95, Copyright (2007), with permission from Elsevier.

Symptoms of brain tumours in young children are often nonspecific and easily dismissed by the physician who first encounters the child. Symptoms may include 'cerebellar fits', which may be mistakenly identified as seizures but are actually acute periods of obtundation, representing incipient coning and dangerous levels of brainstem compression due to a tight posterior fossa. Visual obscurations may also indicate high intracranial pressure. Their presence heightens the urgency of surgical intervention. Symptoms may intermittently 'come and go', with the child appearing neurologically intact, giving the impression of a 'functional' cause, and thereby delaying diagnosis. Previous studies focusing on delayed diagnosis found that the median period between the first presenting symptom to diagnosis (prediagnostic symptomatic interval or PSI) was about 2 months, and was inversely related to the child's age (Kukal et al., 2009). PSI also correlated with tumour histology. High-grade tumours associated with a shorter PSI and low-grade tumours associated with a longer PSI. Kukal et al. also showed that PSI is not independently associated with the prognosis, but rather, there is an association with the tumour histology and patient age.

Head circumference is an essential component of the examination, particularly in infants, and should be recorded on a head circumference chart. Visual decline is often missed in young children until the loss is advanced, because the child does not notice or report it. Vision should be formally tested if possible. Visual fields and acuity should be recorded, particularly if there is a possibility that the lesion involves the visual pathways. Sluggish dilated pupils are a sign of severely raised intracranial pressure and are a warning sign of impending neurological deterioration. Only about 20% of children with PBTs will have papilloedema and about 50% of them will have a normal neurological exam. Therefore, taking a careful history may be more important than the actual examination (Shay et al., 2012). Hearing should be formally tested too, particularly if there is developmental delay or if the lesion is likely to involve hearing pathways.

Paediatric neurologist and paediatrician

It is helpful to involve a paediatric neurologist during the diagnostic phase, particularly if there is a complex neurological picture or epilepsy is a feature. There may be general medical problems, and/or developmental, behavioural, and family issues which require the expertise of a paediatrician. Preoperative speech pathology and physiotherapy assessments may also be relevant. Paediatric neurologists, as the gatekeepers for magnetic resonance (MR) in many Western countries, have to be trained in differentiating between important and unimportant signs of PBTs. To achieve an upward learning curve, an open line of communication must be established between paediatric neurologists, and paediatric neurosurgeons.

Neuropsychology and developmental assessment

A baseline neuropsychology assessment should be completed preoperatively for children over the age of 4 years. Some limited neuropsychological testing can even be done in some 3-year-old children. Formal developmental assessment with the Vineland Adaptive Behavior Scale can also be performed on children less than 3 years of age. Results of any neuropsychology assessment may be obfuscated by raised intracranial pressure or mood change. Nevertheless, it will be helpful in determining prognosis for recovery of cognitive function postoperatively and also has important medicolegal implications.

Endocrinology

Any child with endocrine or growth disturbance identified preoperatively, as well as any child with the possibility of endocrine complications postoperatively, should be assessed preoperatively by endocrinologists. Weight, height and, when relevant, pubertal status of the child should be documented and their nutritional state and fluid balance assessed.

Endocrinopathy is common among children with craniopharyngiomas, as well as children with optic pathway/hypothalamic gliomas. Endocrinological screening is important preoperatively, as well as postoperatively, as major endocrinopathies may follow treatment.

Epilepsy

Epilepsy should be fully characterized and preferably investigated by an electroencephalogram (EEG) or in cases of more frequent epilepsy by video-EEG monitoring. All focal seizure investigations should include MR imaging. An attempt at controlling the epilepsy should be made prior to surgery. Prophylactic anticonvulsants are usually commenced preoperatively for supratentorial pathologies; however, this remains a controversial issue (Fattal-Valevski et al., 2013).

Neuroimaging

Complete CNS imaging (including spinal imaging) is important in order to define the goals of surgery—total gross resection on one extreme, as opposed to biopsy on the other. Figures 88.1–88.4 present typical images of various paediatric brain tumours.

MR with gadolinium-DTPA contrast is superior to CT, defining the exact location and extent of the tumour, and aiding with planning the tumour resection.

MR should be obtained for all patients preoperatively. The sagittal and coronal images are particularly helpful for midline tumours, showing the tumour relationship to the brainstem, the ventricular system, and other surrounding structures, and thus aiding in the planning of surgery. When dealing with potentially metastatic tumours (such as germ cell tumours, ependymomas, and medulloblastomas), spinal screening MR should be completed along with cranial MR in order to detect spinal metastases and leptomeningeal spread before blood enters the canal during surgery and makes it more difficult to distinguish between blood and tumour. Diffusion-weighted and perfusion MR imaging may help characterize the tumour, and assess treatment response.

New white matter protocols with diffusion tensor imaging (DTI) have lately become useful in identifying functional pathways and their relation to the tumour. Especially when integrated into navigation workstations, DTI may increase surgical safety.

It is important to note that some children are diagnosed following an acute event. Thus a CT scan, which is quick to perform with greater availability than MR, is often the primary diagnostic tool. CT is superior to MR in defining skull involvement, or for demonstrating tumour related calcifications (such as in craniopharyngiomas), and is extremely important when evaluating skull base tumours that may invade the skull. However, these tumours are uncommon in children. Navigational/stereotactic techniques should be planned, and designated fiducial markers placed on the child's head prior to imaging.

A variety of other imaging tools are available, and useful within the proper context. Brain ultrasound (US), especially in small children with open fontanelles, may serve as a screening tool, but an MR is absolutely indicated for further evaluation. MRS has been used in various applications, for diagnosis, differentiation between tumour recurrence and radiation necrosis, tumour follow-up, and prognosis.

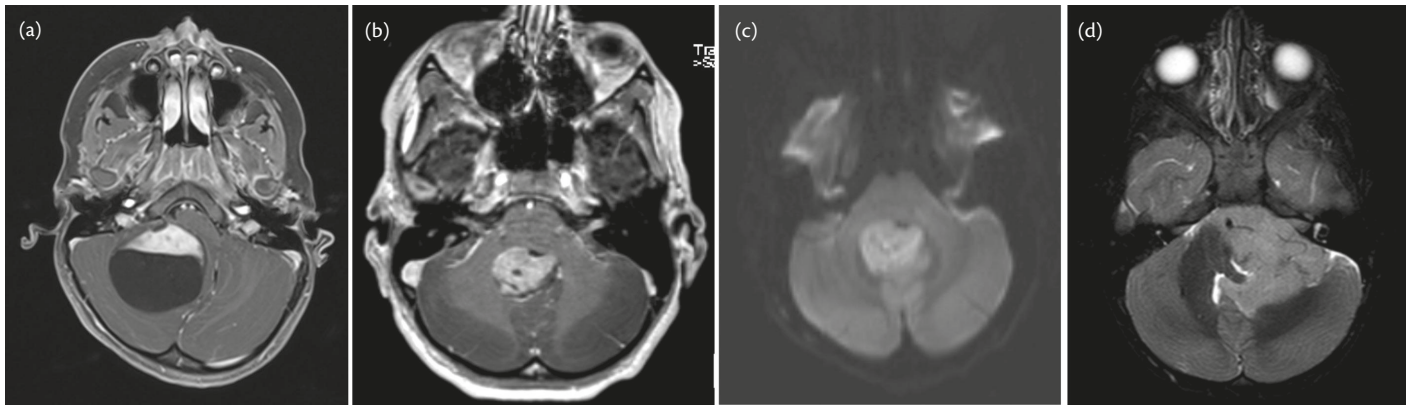

Fig. 88.1 Typical posterior fossa tumours in children: (A) pilocytic astrocytoma; (B and C) medulloblastoma; (D) ependymoma.

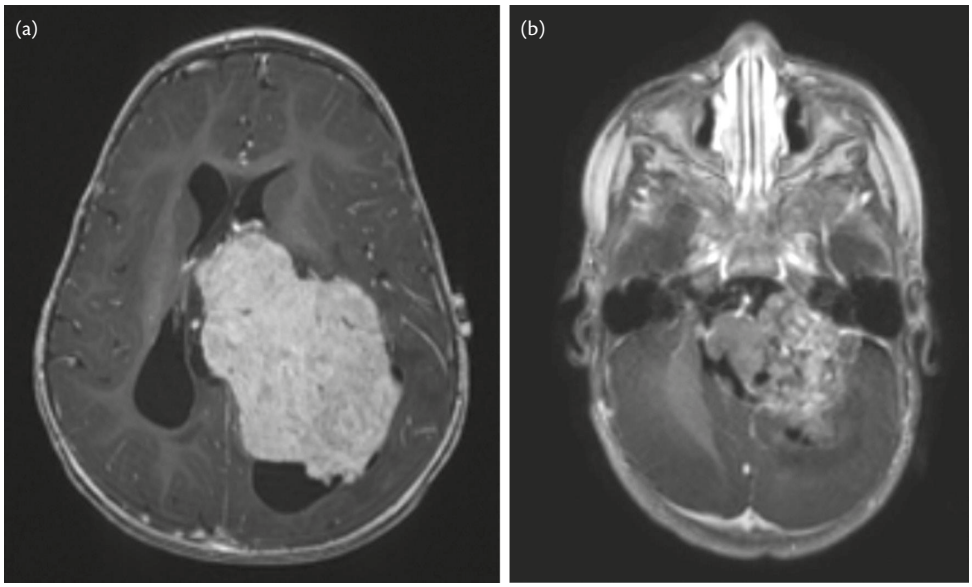

Fig. 88.2 Infantile tumours: (A) choroid plexus papilloma; (B) posterior fossa atypical terato-rhabdoid tumour (ATRT).

The sensitivity and specificity of MRS is not high, and thus MRS can only be used as a complementary tool to other studies or histological diagnosis. Nuclear medicine has a role in diagnosis and follow-up for children with brain tumours. Bone scans can be useful for showing 'hot areas' for skull-involving tumours such as Ewing sarcoma and osteosarcoma. FDG PET scans shows hypermetabolism related to tumours but this technique has a low spatial resolution and is also a complementary investigation. Similarly, SPECT scans may show increased uptake, especially in astrocytomas, but these too serve as complementary investigations.

Timing of neuroimaging

Neuroimaging is warranted whenever a new neurological deficit occurs; whether motor, cranial nerve-related, or an abnormal ophthalmological finding. Torticollis may be suggestive of a craniovertebral or a posterior fossa lesion; thus, when no other cause explains a new onset torticollis, CNS imaging is indicated. Neuroimaging is also indicated for enlarging head circumferences beyond the baseline growth curve, suggesting hydrocephalus or an intracranial mass.

New onset of a seizure disorder may be the presenting sign of a brain tumour. Yet most seizures among children are not secondary to tumours, but secondary to cortical dysplasias, trauma, and metabolic diseases. The role of MR in the workup of an unprovoked seizure in a child has been discussed in the literature. Less than 0.5% of children were shown to have a brain tumour. Currently, based on the available data, MR following an unprovoked seizure remains a recommendation. MR should be done emergently if the child remains with a focal deficit that does not resolve within several hours (such as in Todd's paresis), or in a prolonged status epilepticus not resolving within hours. A non-urgent MR is recommended following an unprovoked focal seizure (with or without generalization), or when the EEG does not suggest a benign epilepsy of childhood, or any other primary seizure syndrome, or in children under the age of 1 year.

Other investigations

Other diagnostic investigations include germ cell tumour markers such as alpha-feto-protein (αFP), beta-human-chorionic-gonadotropin (βHCG), and placental alkaline phosphatase in the serum and CSF. The presence of these markers serves in some treatment protocols as a major indicator for decision-making, as well as a baseline marker for tumour follow-up (Echevarria et al., 2008).

Dexamethasone

Steroids are often commenced several days before surgery to reduce peri-tumoural oedema. The child's condition often improves noticeably with this medication. One should avoid the cushingoid effects of prolonged high doses.

Incidental brain tumours

Rising numbers of MR scans, performed during evaluations for paediatric disorders, have contributed to a significant increase in the number of incidentally found brain tumours. Currently, there is very little literature on the nature and preferred treatment of these incidental brain tumours. In a recent study, Roth et al. summarized 47 incidental tumours diagnosed at two centres (United States, Israel). Only three were eventually diagnosed as high-grade tumours. They summarize that many lesions are benign and may be closely followed (beginning with every 2–3 months); however, an individualized approach should be applied depending upon suspicion of malignancy in the imaging, changes in lesion size or enhancement, changes in neurological status, surgical risk, and parental preferences (Roth et al., 2012).

Tumours that do not need a biopsy or resection

Several paediatric brain tumours are diagnosed solely based on radiological and clinical appearance and need not go on to resection or even biopsy. These tumours may cause secondary effects such as hydrocephalus, which may need to be treated, but oncological treatments may be given with no tissue specimens. These include: classical diffuse intrinsic brainstem glioma (DIPG), classic tectal glioma, bifocal tumour (pertaining always to germinomas), optic pathway glioma (especially when associated with neurofibromatosis type 1), and subependymal giant cell astrocytoma (when associated with tuberous sclerosis).

Operative principles

The goals of surgery are to accurately define the extent of the tumour including the presence of leptomeningeal deposits, to resect as much of the tumour as can be achieved without causing further significant neurological deficit, and to correct secondary hydrocephalus and re-establish CSF pathways. Maximizing the extent of resection while minimizing morbidity is achieved using operative adjuncts such as intraoperative navigation systems, real-time imaging, and preoperative as well as real-time functional monitoring. In the following section we address the various factors that are used to achieve these goals. The goal of resecting maximal tumour is modified for specific tumour types such as germ cell tumours, which are very sensitive to adjuvant therapy. Collection of CSF for cytology and tumour markers has important prognostic implications for those tumours with a propensity to seed into the CSF pathways. Note that lumbar CSF has much better predictive value and higher positively rate than ventricular CSF (Gajjar et al., 1999).

Physiology of the child

The child is not a small adult, and the surgeon must be aware of the differences in surgical and anaesthetic techniques required for children compared to adults. This particularly relates to airway considerations, blood volume, thinness of the scalp and skull, delicacy of the tissues, surface area to weight ratio, intravenous fluid requirements, and drug metabolism. The child is easily prone to hypothermia, hypovolemia, and anaemia, all of which should be prevented. The young child needs a particularly gentle approach both in general body handling and during surgery, and the surgeon must minimize blood loss with meticulous haemostatic techniques.

In addition, the sulci and Sylvian fissure are not well developed in young children, and are not as readily used as planes of dissections or surgical corridors as in the mature brain.

Timing of surgery

The child with a posterior fossa tumour and obstructive hydrocephalus is in a parlous situation and provides a challenge for the neurosurgeon, particularly in relation to the timing and order of surgery. The hydrocephalus is usually controlled following the definitive removal of the tumour, but the conscious state is an important determinant of the timing of surgery. An obtunded patient is an urgent surgical problem requiring prompt action. Steroids may delay the urgency of surgery if the conscious state is only mildly disturbed. The

patient should be placed on the next elective list unless obtundation is present, in which case the operation should be done forthwith. Placement of a ventricular drain may be hazardous in the presence of a large posterior fossa tumour, because upward coning and secondary haemorrhage in the brainstem may occur and cause further obtundation and blindness due to the compression of the posterior cerebral arteries at the tentorial edge. The risk of upward herniation is reported to be 3% (Albright, 1983), with a higher risk for large vermian tumours. The treatment is occlusion of the drain, and immediate resective surgery. Third ventriculostomy is an alternative to an external ventricular drain.

It is preferable to proceed immediately with the definitive excision of a posterior fossa tumour rather than initially treating the hydrocephalus. Even if the patient presents obtunded, immediate placement of an external ventricular drain and resection of the tumour is advised, because the tumour itself may be causing considerable brainstem compression and contributing to the obtundation. In such a case, the ventricular drainage and pressure reduction should be minimal until the posterior fossa has been decompressed, to prevent upward herniation. If the patient has been vomiting for a prolonged period, is dehydrated with electrolyte disturbance, poorly nourished, in poor general condition, and also obtunded, it may be necessary to correct the hydrocephalus first with controlled CSF drainage. This will render the patient in a better general condition for major resective surgery. The patient must be observed very closely for any deterioration due to coning or increasing brainstem compression.

Obstructive hydrocephalus due to pineal region tumours is best managed with an endoscopic third ventriculostomy. The tumour can be biopsied at the time of the third ventriculostomy (Roth and Constantini, 2015). Tumour excision may follow as a secondary procedure if indicated (Cultrera et al., 2006). Aqueductal tumours are a unique entity that have recently been described. The surgical implications include technical nuances with the endoscopic third ventriculostomy and biopsy (Roth et al., 2015).

A controversial issue is a small tumour presenting with a seizure, with no mass effect or secondary hydrocephalus. Despite the lack of literature, it seems that the transformation of low-grade tumours to high-grade ones is extremely rare among children. It may thus be an acceptable treatment to follow intact children with small tumours that appear as low grade on the imaging and present with seizures, as long as the imaging characteristics remain stable, and their seizures are controlled medically.

Positioning

The position of the child depends essentially on the location of the tumour. The surgeon must have a direct line of sight to the tumour and comfortably reach the tumour's extremities. The prone position is commonly used for posterior fossa tumours and occipital supratentorial lesions.

The surgeon must weigh risks versus benefits when choosing the sitting position. There are some high vermis, brainstem, or pineal lesions extending predominantly infratentorially which are better suited to the sitting position compared with the prone position, but each case must be judged individually and depends on the surgeon's experience. The sitting position is not usually chosen in children under 4 years of age. The advantages of the sitting position are that the exposure of the tumour may be excellent, microscope access is improved, and haemorrhage and brain swelling are minimized. The disadvantages are that the surgeon must sit in an awkward and uncomfortable position, operating with arms elevated and extended for often prolonged periods, and may become fatigued. In addition, the patient has cardiovascular instability with a tendency to postural hypotension, and the risks of venous air embolism (VAE) and paradoxical air embolism are enhanced. The latter is rare, but its effects are disastrous. The risk of air embolism in children, as in adults in the sitting position, is 30–45%, and children are more frequently endangered by this complication than adults. A discussion of the methods of detection, clinical effects, therapy, and prevention of VAE is beyond the scope of this chapter but is developed further in the literature (Jadik et al., 2009). Pneumocephalus, intracranial hematoma, and cerebral hypoperfusion may also occur in the sitting position. The lounging position, with hips flexed and knees flexed up to near shoulder height, maintains the advantages of the full sitting position, while significantly lessening the risks of hypotension, reduced cerebral blood flow, and air embolism.

Application of three-point head fixation must be done very carefully between the ages of 18 months and 5 years, and should not be used below the age of 18 months. CSF leaks and depressed skull fractures may easily result if too much pressure is applied. A combined horseshoe and pin system has been suggested for children from 6 months to 14 years of age (Gupta, 2006).

Neuroanaesthesia

An arterial line, pulse oximeter, and urinary catheter should be placed prior to positioning the patient. Excessive neck flexion should be avoided in the prone position, and the chin should not touch the chest. The eyes need careful protection, particularly when the patient is prone. Towels should be placed and held on either side of the head to prevent any antiseptic preparation entering even fully covered eyes. Careful padding of the face, and especially the eyes, is required for the prone position on the horseshoe ring. The surgeon should check that the patient's eyes are not in close contact with the horseshoe ring itself. The surgeon should also check the peripheral cutaneous pressure points for adequate protection with soft padding. A securing adhesive plaster or silicone bar are placed under the child's buttock, to prevent the child from gliding during tilting of the operative table. Kinking of the endotracheal tube is not usually a problem in either sitting or prone position if nasal intubation is used. Once the patient is in the final position, the anaesthetist will need to check the position of the endotracheal tube to ensure that it has not entered the right mainstem bronchus.

Prophylactic broad-spectrum antibiotic cover is given at the time of induction. We currently use vancomycin and ceftriaxone, or cephalothin. Careful attention should be directed to maintenance of body temperature, particularly in the younger child, because hypothermia is a consequence of undue periods of body exposure. Further intravenous steroids are administered at induction. It is not necessary to administer anticonvulsants for a posterior fossa tumour. If the cranial contents appear tight radiologically, mannitol is administered intravenously in a dose of 0.25–0.5 g per kg at the time of the scalp incision. This helps reduce intracranial pressure and aids operative exposure. The cerebral protective effect may also

be helpful. Precordial Doppler and end-tidal CO_2 monitoring are performed when the patient is in the sitting position.

Surgical approaches

The surgeon must exercise flexibility and versatility of approach to achieve the safest and usually the most direct route to the tumour. For tumours involving the base of the skull or the basal cisterns, the same principles as apply to adult skull base surgery should be applied to the child. The aim is maximal exposure of the lesion with minimisation of brain retraction. Skull base approaches are increasingly being used in children to enable resections of tumours such as chordomas, meningiomas, and sarcomas. The transsphenoidal approach may be indicated for some selected sellar and parasellar lesions (Kassam et al., 2007). This approach is suitable for intrasellar craniopharyngiomas and those with a globular suprasellar extension (infradiaphragmatic), as well as pituitary tumours. The transnasal transsphenoidal approach using endoscopy is well suited to the child's small nasal passages (Kassam et al., 2007).

Adjuncts to operative neurosurgery

Stereotaxy

Various technical adjuncts to tumour excision are being used to increase the precision of brain tumour surgery and to decrease morbidity. Intraoperative ultrasound is a simple method for identifying larger subcortical lesions. Frameless stereotaxy is becoming an indispensable aid to brain tumour surgery, enabling the surgeon to accurately plan the trajectory, choose the entry point (enabling smaller craniotomies in many cases), and provide useful intraoperative navigation (Roth et al., 2006). Frameless stereotaxy may be used for stereotactic biopsies; however, framed stereotaxy is advisable for biopsy of small deep-seated lesions.

Neuroendoscopy

Transventricular endoscopic procedures have become commonly used for various pathologies. CSF drainage-related procedures, such as endoscopic third ventriculostomy (ETV) and septum pellucidotomy, are being widely used (Oertel et al., 2009). In addition, endoscopic resection of intraventricular tumours has been described in patients with and without hydrocephalus (Souweidane, 2008). In patients with obstructive hydrocephalus secondary to midline tumours (pineal, tectal, thalamic), the common practice is endoscopic biopsy with or without an ETV (Roth et al., 2015; Roth and Constantini, 2015). Use of fine 1–2 mm malleable fiberscopes can provide the surgeon with unparalleled views of the tumour and the tumour bed at close range and from unusual angles. This technique may enable the surgeon to minimize surgical morbidity and to improve the completeness of the excision. The endoscope and frameless stereotactic system can be combined to improve placement and navigation of the endoscope (Souweidane, 2008).

Functional magnetic resonance (fMRI) and diffusion tensor imaging (DTI)

Preoperative functional MRI (fMRI) based on blood-oxygen-level-dependent (BOLD) images can be used in cooperative children from about the age of 5 years to identify the side of speech dominance with some confidence (Hertz-Pannier et al., 2014). fMRI localization of the sensorimotor cortex can be integrated into frameless stereotactic images, correlating accurately with electrophysiological localization of the sensorimotor cortex. Coregistration of the fMRI speech cortex localization into the frameless stereotactic system can also be performed. This technique may prove useful to more confidently resect tumours which lie close to or within the language or sensorimotor cortex.

DTI has been used for imaging reconstruction of the main white matter tracts, such as the pyramidal tracts (Hendler et al., 2003). Combination of preoperative DTI with navigation may additionally aid intraoperative identification of the highly functional white matter tracts, thus assisting the surgeon during removal of intra-axial tumours situated near the pyramidal tract, such as brain stem tumours or cerebral tumours adjacent to the thalamus or motor tracts.

Resting state fMRI has emerged as a novel way for studying large scale networks by measuring connectivity. The basis for rsfMRI is spontaneous activity rather than task induced activation or BOLD. Currently rsfMRI has a low precision in identifying specific networks with potential surgical implication; however, this is an emerging tool with potential implications in the paediatric population (Hertz-Pannier et al., 2014).

Electrophysiological monitoring

Electrophysiological monitoring includes several modalities, such as motor evoked potentials (MEP), somatosensory evoked potentials (SSEP), brain stem auditory evoked responses, cortical stimulation, and cranial nerve nuclei stimulation (Sala et al., 2002). MEP and SSEP provide continuous monitoring during resection of lesions that are adjacent to the pyramidal and sensory tracts. The most common anatomical areas for these lesions are brainstem tumours. Early identification of a decrease in MEP or SSEP response alerts the surgeon to potential damage, and helps to tailor the surgery for maximum resection while also maximizing patient safety. Cortical stimulation (either in an awake patient or with the aid of EMG recording in an anaesthetised patient, without muscle relaxants) helps identify the motor strip and plan a non-eloquent corridor for surgery. In young children, while the motor thresholds are too high under general anaesthesia to obtain an accurate motor map, SSEP can be used successfully to identify the sensory cortex. SSEP or a phase reversal may be measured or defined using an electrode strip.

Cranial nerve nuclei stimulation aids in resection of brainstem tumours. Stimulation of the brainstem surface (usually the fourth ventricular floor) maps functional areas, thus again aiding in finding a non-functional corridor to the tumour (Morota et al., 1996).

Cortical mapping versus awake craniotomy

Cortical mapping is useful for resection of lesions close to or within the speech or sensorimotor cortex. It is possible to perform electrical mapping of the cortex in awake patients over the age of 8 years, but this is a very unpleasant experience for the child. In the Toronto group, out of 610 patients the youngest was also 12 years old (Serletis and Bernstein, 2007). If mapping of the speech or motor cortex is required prior to the definitive resection of a tumour in a child, we would prefer to insert cortical electrode grids, map the cortex extraoperatively, and resect the lesion at a second stage procedure. This two-staged approach is usually used when the child has

an epileptic focus and a structural lesion. The standard grids have electrode spacing of 1 cm, which does not permit accurate mapping using extraoperative stimulation. Special grids with an electrode spacing of 0.5 cm are required.

Intraoperative imaging

Real-time intraoperative imaging systems enable navigation based upon images acquired intraoperatively. These imaging systems consist of intraoperative MR (iMR) scanners, CT scanners, or ultrasound (US) systems. By obtaining intraoperative images, the navigation data set may be updated during the operation, thereby compensating for anatomical changes such as brain, tumour, or cavity shifts (Roth et al., 2006). Using iMR systems for navigational imaging and postoperative imaging alleviates the need for routinely requiring additional preoperative and early postoperative CT or MR scans. Intraoperative MR systems acquire images in a variety of sequences, such as T1 (with or without contrast), T2, and FLAIR, thereby differentiating pathological tissue from normal brain tissue and maximizing resection control. Contrast-enhanced fast FLAIR MR provides marked contrast enhancement clearly showing tumour boundaries and is a sensitive method of detecting residual or recurrent tumour (Essig et al., 1999). Note that in the paediatric population, complete resection of low-grade gliomas has been shown to be a good prognostic factor (Black, 2000; Cohen et al., 2001).

The intraoperative ultrasound (IOUS) system enables acquisition of high-resolution IOUS images. Combined with 3D reconstruction used as a basis for navigation, the new, updated images are presented simultaneously with preoperative image reconstructions in the same spatial orientation, to improve anatomic orientation. IOUS such as the SonoWand system have shown similar results differentiating normal brain tissue from glial tumours (Tronnier et al., 2001). In certain cases, the tumour to tissue resolution is even better using the IOUS system, especially when comparing high-end US equipment with low-end iMR machines (Roth et al., 2007). The IOUS system maximizes the accuracy and efficiency of neuronavigation, enabling surgeons to fine-tune the resection with optimal effectiveness.

Postoperative care

Intensive nursing is provided in the general ward or the neurointensive therapy unit, depending on the magnitude of the surgery. Any potential or manifest endocrine deficiency or hypothalamic thirst centre dysregulation will require close monitoring and management by the paediatric endocrinologist, and ongoing epilepsy may require the ongoing involvement of the neurologist.

Additional aspects that require special emphasis in the postoperative care of children following brain tumour surgery are the requirement for adequate analgesia. This may involve patient-controlled analgesia for older children, or carefully monitored opiate infusion for younger children. Postoperative neurological deficits such as cerebellar symptoms and mutism after posterior fossa surgeries, cranial neuropathy after brainstem involving procedures, and/or nausea and vomiting after procedures adjacent to the obex, all cause additional discomfort and stressful impact on the child and the family. Thus, there is often a need for rehabilitation taking place in an environment that includes specialist paediatric providers. Additionally, there is need for family counselling and support.

In the long-term, children with brain tumours have the potential for a normal quality of life (Kulkarni et al., 2013). Thus, every effort should be applied to restore function following diagnosis and treatment.

Timing of postoperative neuroimaging

Identification of residual or recurrent tumour is critical in planning therapy, determining the response to therapy, and the prognosis. Surgically induced MR-detectable contrast enhancement and extracellular methaemoglobin formation all occur within 24 hours of the completion of surgery, interfering with the detection of small amounts of residual tumour. It is often difficult to perform a scan within this time frame. It is important to perform a postoperative cranial MR within 72 hours of surgery, usually giving a good indication as to the completeness of the excision. If the tumour has a propensity to metastasize, a spinal MR scan should be included if it could not be done preoperatively, but the surgeon should be aware that blood in the spinal canal from posterior fossa surgery will obscure any pathology for several days.

Surveillance neuroimaging protocols should be developed for each tumour type to minimize the number of postoperative scans required to most likely yield a positive result based on the frequency of recurrence. Surveillance imaging timing should be tailored according to the tumour grade/malignancy, and are useful for both low- and high-grade tumours.

Reoperation or 'second look' surgery

Reoperation for residual disease may be indicated to obtain a complete clearance of tumour. This particularly applies to ependymomas or choroid plexus tumours, where complete excision is the most important factor affecting long-term survival. Several operations may be required to achieve this aim if the tumour is accessible. Intraoperative imaging will verify the total resection of the tumour, and reduce the need for second look surgery.

Interpretation of the pathology

Paediatric neuropathology is a challenging discipline because of the wide range of often uncommon tumour types with often subtle and variegated histological features. Prognostication based on paediatric neuropathology is less predictable than the adult equivalent. This is especially so in the case of gliomas with anaplastic features. Unusual tumour types have been described in children such as the desmoplastic glioblastoma of infancy (Al-Sarraj and Bridges, 1996), pleomorphic xanthoastrocytoma, the atypical teratoid/rhabdoid tumour which can be mistaken for glioblastoma and PNET tumours (Parwani et al., 2005). The teratoid/rhabdoid tumour is very aggressive in behaviour, with a poor response to chemotherapy, and should be separated from the medulloblastoma group, otherwise any analysis of results and response to chemotherapy is skewed (Squire et al., 2007). Atypical choroid plexus papilloma needs to be differentiated from both choroid plexus papilloma (CPP) and carcinoma

(CPC). The increasing emphasis on tumour markers, immunocytochemistry, proliferation indices, and cytogenetics to more accurately classify brain tumours and predict their behaviour are discussed elsewhere in this book.

Tumour seeding via shunt systems

The development of extraneural metastasis is uncommon following the placement of a ventriculoperitoneal or ventriculoatrial shunt (Pollack et al., 1994). Medulloblastoma confers the greatest risk. Pineal tumours may also metastasize this way. Children with optic pathway gliomas which harbour shunts, tend to develop ascites at higher rates compared to other pathologies.

Adjuvant treatments

The role of surgery changes according to the specific tumour type. Tumours that are treated solely by an aggressive surgical approach include some ependymomas, low-grade gliomas (including grade 1 and 2 astrocytomas), choroid plexus papillomas (including atypical), pituitary adenomas, and most meningiomas.

However, certain tumours may not be amenable to total resection without a significant associated morbidity due to their invasion of critical structures, such as the brainstem, optic tracts, and hypothalamus. Some tumours have a high recurrence rate despite 'total gross resection', this may be secondary to local invasion (such as in high-grade gliomas, CPC, and medulloblastomas), or to concurrent metastasis (e.g. medulloblastomas, ependymomas, germ cell tumours).

Thus, over the years, various adjuvant treatments have evolved, including radiation-based treatments and chemotherapeutic regimens.

Certain tumours are extremely sensitive to adjuvant treatments. When weighing the risks and benefits of the various treatments (including surgery, chemotherapy, and radiation), the logical decision for some tumours is to treat mainly by chemotherapy and/or radiation, while surgery (if at all) is applied for diagnosis only. A classic example of this approach is treating germ cell tumours. These typically midline lesions occur either in the suprasellar area or in the pineal region. These tumours are extremely sensitive to chemotherapy and radiation. Over the last few years, their diagnosis and treatment has shifted from surgical resection, to diagnosis based on serum (or CSF) markers—αFP, βHCG, and placental alkaline phosphatase. Only if all markers are negative is there an indication for a biopsy (Echevarria et al., 2008). However, when presenting with obstructive hydrocephalus from aqueductal compression, these patients are treated by an ETV and endoscopic biopsy (Shono et al., 2007).

Another example of treatment paradigm shift is in the treatment of craniopharyngiomas. This is a benign tumour, typically situated in the suprasellar region, often rising into the third ventricle. Until a few years ago, the ultimate treatment was a total gross resection. Despite a low recurrence rate, the neurocognitive and hormonal outcomes were dismal, mostly from injury to adjacent structures along the hypothalamic-pituitary axis. While surgery is still the primary treatment, with maximal resection as the goal, additional and effective adjuvant regimens enable a less aggressive surgical approach, with lower surgery associated morbidity and good tumour control. These treatments include radiation, intralesional chemotherapy (such as bleomycin or interferon), and intratumoural radiation (Puget et al., 2006).

As the focus of this chapter is the surgical aspect of paediatric brain tumours, we will only provide a brief review of the adjuvant treatments, focusing on their essentials and the major relevant tumour subpopulations.

Radiation

For many childhood CNS tumours, radiation therapy plays an essential role in treatment. For most childhood brain tumours, chemotherapy cannot eliminate all the cancer cells, thus radiation is frequently employed. Despite the beneficial oncolytic effect of radiation therapy, there are potential, mostly long-term complications. The developing immature brain is vulnerable to radiation, particularly the white matter (Kitajima et al., 2007).

Neurocognitive decline, neuroendocrinopathy, cranial neuropathy, retinopathy, vasculopathy (including secondary moyamoya disease), myelopathy, and spinal growth disturbance are all secondary to injury of the developing brain, spine, and adjacent structures.

Secondary cavernous angiomas secondary to microvascular injury may occur (Duhem et al., 2005). Secondary tumours (benign, such as meningiomas, and malignant, such as high-grade gliomas and thyroid carcinoma) occur due to various genetic insults, and may occur many years after the radiation treatment (Umansky et al., 2008). The risk of secondary tumours may be higher among syndromatic children, such as those with neurofibromatosis and nevoid basal cell carcinoma syndrome (Kleinerman, 2009).

We do not advise whole brain radiotherapy in children before the age of 3 years because of the long-lasting and often profound effects on cognitive development and neuroendocrine function.

Due to all the risks of general radiation, the improved precision of conformal radiation techniques has been increasingly utilized to treat paediatric brain tumours.

Stereotactic radiosurgery has been applied in children for treating tumours and arteriovenous malformations. The advantage of this technique is the steep target to periphery radiation exposure dose cut off. However, controversy still exists concerning the safety of radiosurgery in children in general, and for pathologies adjacent to crucial structures, such as the brainstem, cranial nerves, and hypothalamus, in particular.

Proton beam therapy is a relatively new radiation technology applied in the treatment of brain and spine tumours. Although only preliminary studies have addressed this technology in PBT, there is currently a shift in radiation technique towards proton beam especially for craniopharyngiomas. Implication of proton treatment for other PBT is under study.

Chemotherapy

Adjuvant chemotherapy has become part of the protocol for most adult brain tumours, and in some paediatric tumours too. In fact,

since in the very young population radiation therapy is associated with devastating neurocognitive and neuroendocrine sequala, the need to add adequate chemotherapy is even stronger.

Chemotherapy may be used as a neoadjuvant treatment prior to surgery especially in high risk surgical patients such as infants harbouring huge tumours, as well as children with choroid plexus carcinomas.

A subset of patients in which chemotherapy has become a valid alternative to surgery is the case with tuberous sclerosis associated subependymal giant cell astrocytomas (SEGAs). These tumours respond favourably to mTOR inhibitors (such as rapamycin and Everolimus), with about 40% of patients reducing their tumour volume by at least 50% over 6 months. mTORi have other positive effects on tuberous sclerosis patients, improving their seizures, renal tumours, rash, and even cognition, thus becoming a disease altering drug.

Paediatric hydrocephalus

Matt Bailey, Chris Parks, and Conor L. Mallucci

Introduction

Paediatric hydrocephalus is the commonest disorder to be managed by paediatric neurosurgeons. Rather than representing a single disease process, hydrocephalus can result from a variety of different pathological processes or insults that culminate in an imbalance of CSF production and absorption. If left untreated the majority of cases are fatal (Laurence and Coates, 1962), but with appropriate surgical management most patients survive, with some leading normal lives into adulthood.

The mainstay of treatment is with CSF shunts, but with technological improvements in imaging and surgical techniques an increasing number are being successfully treated with neuroendoscopic procedures. The disorder can be complex to manage, with many patients requiring multiple surgical procedures and lifelong follow-up.

This chapter gives an overview of paediatric hydrocephalus, its causes and classification, management with shunts and endoscopy, description of surgical techniques, and the outcomes of surgical care.

Definition

The word hydrocephalus is Greek coming from the words: *hydro*, meaning water and *cephalus*, meaning head, its literal translation therefore being water in the head (Orešković and Klarica, 2011). It generally refers to a disorder of cerebrospinal fluid physiology that results in an abnormal expansion of the cerebral ventricles, typically associated with raised intracranial pressure (Kahle et al., 2015).

There is currently no universally accepted definition of hydrocephalus, although several have been proposed over the years. The following definition proposed by Rekate in 2008 has been accepted by many within the surgical community: 'Hydrocephalus is an active distension of the ventricular system of the brain resulting from an inadequate passage of cerebrospinal fluid from its point of production within the cerebral ventricles to its point of absorption into the systemic circulation' (Rekate, 2008a).

The pathophysiology of hydrocephalus is discussed in Chapter 92.

Incidence and epidemiology

The overall incidence and prevalence of hydrocephalus is difficult to ascertain as it can occur in isolation or in association with a variety of neurological disorders. The reported incidence of congenital hydrocephalus ranges from 0.6–0.8 per 1000 live births (Blackburn and Fineman, 1994; Persson et al., 2005; Persson et al., 2007; Jeng et al., 2011), however, many cases of hydrocephalus occur secondary to other disease processes (e.g. prematurity, tumour, infection, trauma). The rates of hydrocephalus are thought to be highest in developing countries, mainly due to higher rates of neonatal infection (Warf et al., 2011). In developed countries the commonest causes are posthaemorrhagic hydrocephalus of prematurity, congenital aqueduct stenosis, myelomeningocele and brain tumours (Kulkarni et al., 2013; Stone and Warf, 2014). Certain factors have been identified that are associated with an increased risk of infantile hydrocephalus: these include low birth weight, low socioeconomic status, male sex and ethnicity where lower rates are seen in those of Asian descent (Jeng et al., 2011; Tully et al., 2015).

Classification of hydrocephalus

At present there is no universally accepted classification system for hydrocephalus and there is an on-going debate on how best to classify the disorder. As hydrocephalus is not a single pathological disease but is a condition of disturbed CSF dynamics that can occur with or without an underlying disease process, its classification can be confusing and complex (Oi, 2011). Two commonly used classifications are congenital versus acquired and obstructive versus communicating hydrocephalus.

Hydrocephalus was classified into obstructive (or non-communicating) and communicating based on work by Dandy in the early 1900s (Dandy, 1919). Dandy and his coinvestigators studied hydrocephalus using ventricular and lumbar punctures. They injected dye into the ventricular system and went on to perform lumbar punctures. If the dye was found in the CSF from the lumbar puncture then the hydrocephalus was classified as being 'communicating'. If no dye was recovered from the spinal tap the hydrocephalus was considered to be 'obstructive'. This classification has stood the test of time and remains the classification by which

hydrocephalus is billed in the United States (Kahle et al., 2015). However understanding of CSF physiology has evolved and remains a matter of debate. The current most widely accepted view is that CSF circulation is via bulk flow with CSF being produced by the choroid plexus within the ventricular system, flowing into the subarachnoid space and being absorbed by the arachnoid granulations to enter the cerebral venous system. Other theories exist and are discussed in Chapter 92.

Since the introduction of modern imaging techniques including computed tomography (CT) in the 1970s and magnetic resonance imaging (MRI) in the 1980s the exact location of sites of obstruction within the CSF pathways can now often be identified. Within the surgical community, the classification system proposed by Rekate (Detwiler et al., 1999; Rekate, 2001) is commonly used as it provides a method for conceptualizing the cause of hydrocephalus in any given patient and applying potential management options (Fig. 89.1).

The identification of the specific point of obstruction allows clinicians to select an appropriate surgical technique tailored to a specific patient (see Table 89.1)

Causes of hydrocephalus in children

The causes of hydrocephalus may be congenital or acquired. Congenital causes include Chiari malformations, spina bifida, Aqueduct stenosis, Dandy-Walker anomalies, arachnoid cysts, and atresia of the foramen of Munro. Acquired causes include haemorrhage, infection, head injury, and tumours (Rekate, 2008b; Kandasamy et al., 2011; Rekate, 2011).

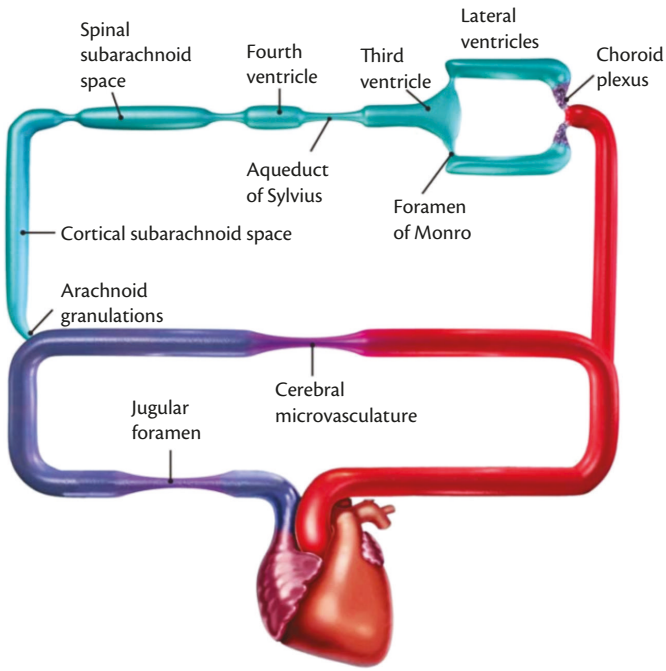

Fig. 89.1 Rekate's classification describes six potential sites where the flow of CSF may be restricted namely the foramen of Monroe; the aqueduct of Sylvius; the outlets of the fourth ventricle; the basal cisterns; the arachnoid granulations; and out flow of venous blood through the dural venous sinuses (Rekate, 2008; Rekate, 2011).

Table 89.1 The treatment options for hydrocephalus caused by obstructions at different points on the CSF pathway

Point of obstruction	Differential DX	Treatments available
Foramen of Monro	Tumour	Shunt (unilateral or bilateral)
	Congenital absence	Endoscopic septum opening
	Ventriculitis	
	Functional	
Aqueduct of Sylvius	Tumour	Shunt
	Birth defect	ETV
	Secondary	
Fourth ventricle foramina	Infection	Shunt
	Tumour	ETV
	Severe Chiari	Surgical opening
Spinal to CSAS	Subarachnoid	Shunt
	Haemorrhage	ETV
	LP shunt	
Arachnoid villi	Haemorrhage or infection	VP or LP shunt
Venous hypertension	Pseudotumor	VP or LP shunt
	Congenital hydrocephalus	Clot lysis
	Sinus thrombosis	Bariatric surgery for obesity-related pseudotumor

Reproduced from Rekate, H. L., A consensus on the classification of hydrocephalus: its utility in the assessment of abnormalities of cerebrospinal fluid dynamics, *Child's Nervous System*, Volume 27, pp. 1535–41 Copyright © 2011 Rekate.

Data from the shunt design trial (Drake et al., 1998), the hydrocephalus research network (Kulkarni et al., 2013) and the UK shunt registry (Richards, 2010) give roughly similar distributions of the most common causes of hydrocephalus in children. Posthaemorrhagic hydrocephalus comprises 25%, other common causes include myelomeningocele, Chiari malformations, tumours, aqueduct stenosis, infections, trauma, and intracranial cysts.

Clinical features of hydrocephalus in different age groups

Despite the many causes of hydrocephalus, the clinical presentation is relatively similar in all pathologies. The main variation seen in presentation is related to the age of the child at presentation and whether the cranial sutures are open or closed.

The cranial sutures normally close between 12 and 18 months of age. Due to the relative dispensability of a neonate's or infant's skull before this time the signs of hydrocephalus can sometimes be subtle and can include failure to thrive, developmental delay, and poor head control. The occipitofrontal circumference (OFC) will increase disproportionately and when plotted on a centile chart will be seen to cross centile lines (Fig. 89.2). Irritability, vomiting, and poor feeding are also common. As the hydrocephalus

(a) A child with sunsetting eyes.

(b) Girl's head circumference chart that allows head growth to be plotted.

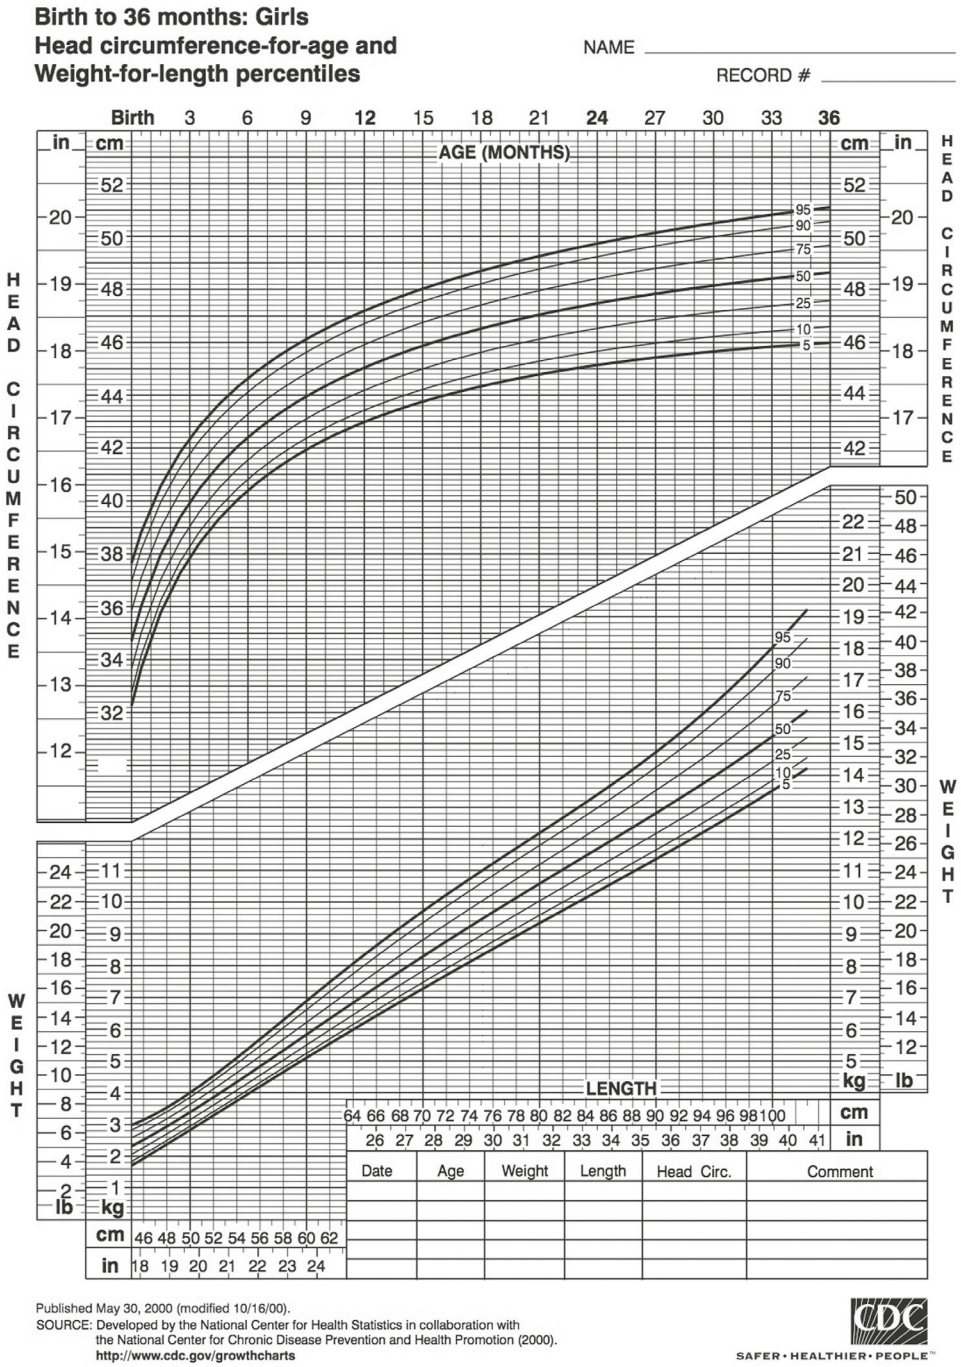

Fig. 89.2 (A) A child with sunsetting eyes. (B) Girls' head circumference chart that allows head growth to be plotted (Kandasamy et al., 2011).

progresses the cranial sutures become splayed, the anterior fontanelle bulges, and scalp veins become engorged. Some infants develop the classic 'sunsetting' appearance where upgaze is lost due to pressure of the third ventricle on the tectum. Ultimately bradycardia, desaturations, and apnoeas can occur. Seizures are not a common presenting feature of hydrocephalus alone and papilloedema is rare in this age group (Abou-Hamden & Drake, 2015). In some cases where the hydrocephalus develops slowly the signs may be few, but invariably the head circumference will have grown disproportionately.

If hydrocephalus develops after the cranial sutures have closed most patients will have a normal head circumference. Subtle signs may include headaches, deterioration performance at school, memory loss, or behavioural changes. More acutely children have symptoms and signs similar to adults with raised intracranial pressure including headaches, vomiting, papilloedema, diplopia (from a sixth cranial nerve palsy), drowsiness, and eventually coma.

The clinical features of hydrocephalus in infants and young children include irritability, impaired level of consciousness, vomiting, failure to thrive, poor feeding, developmental delay, head

circumference crossing the centiles, poor head control, tense anterior fontanelle, dilated scalp veins, sunsetting eyes, bradycardia, apnoeic spells, and seizures. In older children, headache, vomiting, drowsiness, diplopia, seizures, impaired upgaze, and papilloedema are the main features.

Imaging studies used in the investigation of hydrocephalus

Cranial ultrasound

Cranial ultrasound is very useful for imaging the brain in the first 12–18 months while the anterior fontanelle remains open and many neonatal units routinely use ultrasound for screening of preterm infants. No sedation is needed and the procedure can be repeated as often as required with no adverse effects. The size and configuration of the lateral ventricles is easily identified on ultrasound but the third and fourth ventricle, cerebral aqueduct and posterior fossa contents cannot be reliably assessed (Dinçer and Özek 2011). Therefore the precise cause of hydrocephalus is rarely confirmed by ultrasound alone and if treatment of ventriculomegaly is required additional brain imaging should be obtained (Dinçer and Özek, 2011).

Computed tomography (CT)

CT is readily available, fast, reliable, and compatible with emergency life support systems. In most cases children do not require sedation for CT as image acquisition times are short. CT demonstrates the size and morphology of the ventricles and can reveal underlying pathologies such as haemorrhage and tumours. The location of obstructions within the ventricular system may also be evidenced by significant dilatation of the ventricles proximal to the obstruction with normal sized distal ventricles (as seen, for example, in aqueduct stenosis) (Dinçer and Özek, 2011). CT is also valuable in the follow-up of patients with CSF shunts as shunt tubing is well demonstrated on CT. However, children with hydrocephalus often require many imaging studies throughout their lifetime and there are concerns about the long-term effects of exposure to ionizing radiation (Koral et al., 2012; Krishnamurthy et al., 2013). In view of this some centres are now using rapid sequence MR imaging for acute assessment and follow-up of children with hydrocephalus (Koral et al., 2012).

Magnetic resonance imaging (MRI)

MRI is the examination of choice for investigation of children with hydrocephalus.

Conventional T1 and T2 sequences are used routinely and provide excellent images of the brain parenchyma and pathological processes (such as aqueduct stenosis, tumours, and Chiari malformations), as well as evaluating the size and shape of the ventricular system. Modern sequences such as 3D CISS, turbo spin echo and cine PC have gained wide acceptance in evaluating the anatomy of the CSF pathways from the ventricles to the cortical subarachnoid spaces and CSF flow at various sites can be scrutinized (Dinçer and Özek, 2011). Fine anatomical detail of membranes within the CSF pathways, such as at the foramen of Munroe, within the cerebral aqueduct, and the outflow of the fourth ventricle can be demonstrated. Likewise, the anatomy of intracranial cysts and septations within multiloculated ventricles can be studied and can prove invaluable in determining the most appropriate surgical procedure for each patient.

Limitations of MRI include relatively long image acquisition times that often require general anaesthesia or sedation in smaller children. However, in the majority of cases there is sufficient time for children to undergo high quality MR imaging prior to surgical intervention. MRI is also extensively used in the follow-up of patients with hydrocephalus for assessment of ventricular size and to demonstrate the results of endoscopic procedures and the position of shunt catheters. Patients with programmable shunt valves may require valve reprogramming after imaging as some valves can be adjusted by the magnetic field.

Increasingly MRI is also being used in the investigation of central nervous system (CNS) abnormalities (including hydrocephalus) in the fetal period where anomalies have previously been identified on maternal ultrasound. MRI can be used to aid clinicians in prognostication.

Management of hydrocephalus in children of different ages

The following section discusses the assessment and management of children of different ages with hydrocephalus. Initially we will focus discussion on the management of hydrocephalus in preterm infants. The management of term infants and children will then be described.

Hydrocephalus in preterm infants

Preterm infants are those born before 37 weeks' gestation. The majority of cases of hydrocephalus seen in these children is secondary to intraventricular haemorrhage (IVH) related to prematurity. The pathophysiology of IVH of prematurity is discussed in Chapter 90.

Approximately 15–20% of infants with a birth weight less than 1500 g will develop IVH (du Plessis, 2009; Robinson, 2012). The lower the birth weight, the higher the risk of developing IVH (Boop, 2005). The presentation of IVH may be catastrophic with rapid neurological deterioration or progressive with reduced alertness, hypotonia and respiratory compromise, or may be clinically silent (Robinson, 2012). Therefore most neonatal units routinely screen preterm infants with cranial ultrasound (US) to detect IVH and, if present, serial cranial US is used to document progression of the haemorrhage and for monitoring of ventricular size. Imaging is used in combination with clinical features to identify those infants who may require treatment for posthaemorrhagic hydrocephalus (PHH).

Pathological studies of infants with IVH suggest that ventriculomegaly can occur in nearly half of these patients, termed posthaemorrhagic ventricular dilatation (PHVD). However, the presence of PHVD does not always represent symptomatic PHH and may be an ex-vacuo phenomenon related to loss of brain substance secondary to venous infarction or periventricular white

matter ischaemia (Boop, 2005). Clinicians must therefore use a combination of imaging and clinical findings to guide the need for potential interventions.

The clinical features of symptomatic PHH include increased rate of head growth (occipitofrontal circumference—OFC) when compared to published normal values, full anterior fontanelle, separation of the cranial sutures and progressive ventriculomegaly on imaging. Some infants also display features of raised intracranial pressure with lethargy, vomiting, apnoea, and bradycardia. By comparison, infants with ex-vacuo PHVD may have an increase in their ventricular indices, but associated with an OFC that does not cross centile lines (or may even fall across centiles), the anterior fontanelle will be soft and the cranial sutures may be overriding (Boop, 2005).

Published rates of symptomatic PHH in infants following IVH range from 22% to 29% and between 9% and 20% require permanent CSF diversion surgery (Murphy et al., 2002; Vassilyadi et al., 2009; Limbrick et al., 2010). The likelihood of infants developing PHH increases with the severity of IVH (Robinson, 2012).

Management of PHH in preterm infants

Once the diagnosis of symptomatic PHH has been made treatment should be implemented. These infants are fragile and generally of low weight. They may also be clinically unstable and many will have other medical comorbidities. It is generally accepted that ventriculoperitoneal (VP) shunts should not be used as the initial treatment strategy for symptomatic PHH in preterm infants. This is because shunt failure rates are unacceptably high in these patients, partially due to the large amount of protein and blood in the CSF increasing the risk of VP shunt blockage (Hislop et al., 1988). Additionally the skin of these babies is fragile, is at risk of breakdown and infection rates may be higher (Robinson, 2012; Whitelaw and Aquilina, 2012). In most centres VP shunts are only inserted once the infant reaches a weight of 2–2.5 kg and is of term age (Whitelaw and Aquilina, 2012; Leonard and Limbrick, 2015). In view of this there is a need to provide temporary treatment for children with symptomatic PHH.

Potential temporizing measures for these infants include serial lumbar punctures or ventricular taps or neurosurgical procedures to insert external ventricular drains, ventricular access devices, or ventriculosubgaleal shunts (VSGS).

Lumbar punctures and ventricular taps

The use of lumbar puncture for temporization of preterm PHH has been investigated extensively. Most authors describe removal of 10 ml/kg of CSF per lumbar puncture (Kreusser et al., 1985; Robinson, 2012; Leonard and Limbrick, 2015) and 20 ml/kg of CSF is considered to be the maximum volume that should be removed, as larger volumes can be accompanied by apnoea, bradycardia and desaturations (Whitelaw and Aquilina, 2012). There is no evidence that serial lumbar punctures reduce the need for shunt placement or avoid progression of hydrocephalus (Mazzola et al., 2014). Serial multiple percutaneous ventricular taps have been used in the past to temporize PHH, however due to associated complications such as 'puncture porencephaly', infection and encephalomalacia most centres have abandoned their use except as a temporizing measure in a clinically unwell child while waiting for definitive surgical management (Hudgins, 2001; Shooman et al., 2009).

Ventricular access devices (VAD), ventriculosubgaleal shunts (VSGS), and insertion technique

The goal of placing a temporary shunt or access device is to delay the insertion of a permanent shunt until the infant is older and has better nutrition and maturity (Robinson, 2012). The two commonly used options are VAD and ventriculosubgaleal shunts. VAD are made up of a length of ventricular catheter attached to a low-profile reservoir. Once *in situ* they allow percutaneous drainage of ventricular CSF through the scalp. Aspiration of 10 ml/kg of CSF can be performed to maintain a stable condition in the infant. A ventriculosubgaleal shunt is similar to a ventricular access device with the addition of a small segment of distal catheter that is coiled within a subgaleal pocket in the scalp. This has the theoretical advantage of allowing continuous CSF drainage and absorption through the subgaleal pocket and therefore sustained relief of intracranial pressure (ICP), rather than the intermittent diversion provided by access devices. We prefer to temporize infants with a ventriculosubgaleal shunt, although the principles of insertion of an access device are similar (**Fig. 89.3**).

The infant is placed supine, under general anaesthesia. Care is taken to maintain normothermia by the use of an inflatable warming mattress and blankets. A single dose of preoperative antibiotics is given. The head is supported in a neutral position on a jelly head ring (Fig. 89.3A). The scalp is palpated to identify the boundaries of the anterior fontanelle. The midline is marked. A curved skin incision is made so that a small burr hole can be placed in the posteromedial aspect of the frontal bone, just anterior to the coronal suture. The curve of the skin incision should be directed towards the midline so that if the infant were to ultimately have conversion to a VP shunt, shunt hardware would not lie immediately beneath the incision. A right- or left-sided approach can be used and is tailored to the anatomy of the patient seen on preoperative imaging. We prefer to avoid the side with a large clot within it in an attempt to reduce the chances of catheter blockage. An electrocardiogram (ECG) dot is placed in the midline at the nasion so that once the drapes are *in situ* the dot can be palpated to help with orientation (**Fig. 89.3B**).

The skin is then prepped with chlorhexidine solution. Sterile swaps are placed around the operative field and held in place with an opsite sheet to minimize contact with the skin. Surgical drapes are then attached to the opsite and swap construct thus avoiding skin contact with the adhesive on the drapes. The skin is delicate and can tear when the drapes are removed and it also protects the endotracheal tube from being accidentally dislodged when the drapes are removed at the end of the procedure (Fig. 89.3C). The shunt system is then assembled on a separate sterile trolley to that being used by the scrub nurse. A length of ventricular catheter cut to size based on measurements performed preoperatively, with the aim of targeting the catheter so that it sits within the lateral ventricle towards the foramen of Munroe, this is usually in the order of 3–4 cm in length. A piece of distal tubing is cut to a length of approximately 15 cm and four or five small holes are cut into the walls of the tubing to allow the egress of CSF. Both are then connected to a burr hole reservoir

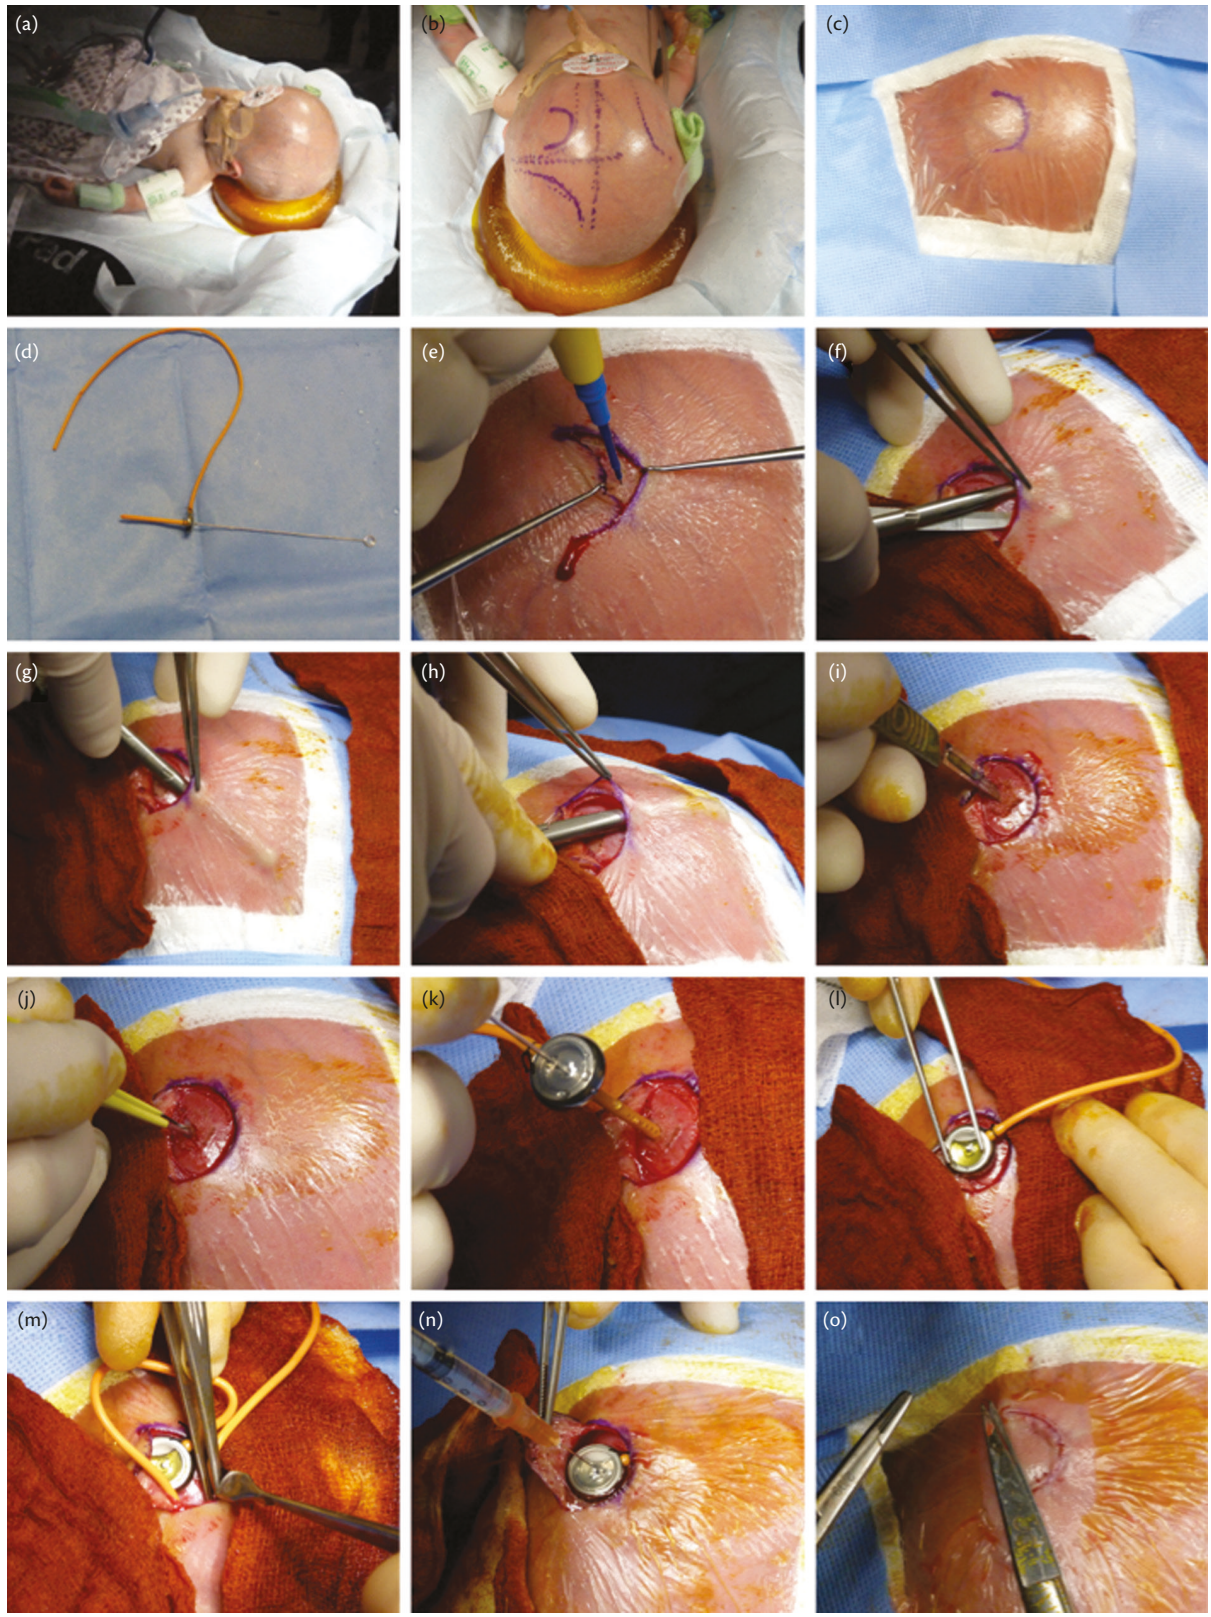

Fig. 89.3 Technique for insertion of a ventriculosubgaleal shunt or ventricular access device.

and secured with silk ties. We then pass the stylet of the ventricular catheter through the reservoir and into the ventricular catheter to facilitate placement and minimize manipulation once the ventricular catheter is *in situ* (Fig. 89.3D).

The skin is cut superficially with a scalpel and the incision is then deepened with monopolar diathermy between skin hooks to minimize blood loss (Fig. 89.3E). The incision is taken through the galea and the scalp flap is reflected and secured with a stay suture. The

pericranium overlying the frontal bone is cut with monopolar diathermy. A large pocket is then created in the subgaleal plane with scissors. Care must be taken to stay in the correct plane to ensure that the anterior fontanelle is not breached. Fibrous adhesions between the galea and the pericranium are divided until one large pocket is produced (**Figs. 89.3F–89.3H**) A 15 blade scalpel is then used in a twisting motion to develop a small burr hole in the frontal bone (**Fig. 89.3I**). This is enlarged with artery forceps. The burr hole need only be large enough to accommodate the diameter of the ventricular catheter. A small nick is made in the dura with a scalpel and the dural edges and cortex are diathermized with bipolar diathermy (**Fig. 89.3J**). The ventricular catheter is then inserted perpendicular to the skull (**Fig. 89.3K**). CSF fills the reservoir confirming entry to the ventricle normally after only a small distance. The stylet is then held still and the ventricular catheter is advanced until the reservoir comes to rest on the skull (**Fig. 89.3L**). A CSF sample is then taken from the system and sent for microbiological analysis (note the xanthochromic CSF in the example). A retractor is used to elevate the subgaleal pocket and the distal tubing is coiled within the pocket (**Fig. 89.3M**). We then instil 5 mg of intrathecal vancomycin into the system via the reservoir prior to closure. (**Fig. 89.3N**) The galea is closed with an absorbable suture (e.g. 4/0 vicryl), and the skin is closed with a similar absorbable continuous suture (**Fig. 89.3O**).

Insertion of a ventricular access device is very similar, the differences being that no distal tubing is attached to the reservoir and no subgaleal pocket is required. We favour ventriculosubgaleal shunts rather than access devices as they require less tapping than access devices (Mazzola et al., 2014) and we feel this reduces the possibility of infection. There is also some evidence that infants treated with VSGS have a reduced need for permanent CSF diversion surgery when compared to patients treated with VADs (Limbrick et al., 2010).

Immediately postoperatively the anterior fontanelle is soft and the profile of the subgaleal shunt tubing is often visible through the scalp. The subgaleal pocket quickly fills with CSF and parents and caregivers should be warned of this preoperatively as the infants often have a marked subgaleal CSF collection. The OFC is monitored daily and the pocket should be examined and palpated. A functioning VSGS will cause a full subgaleal pocket but the cranial sutures should not be splayed, the anterior fontanelle (if palpable) will be soft, and the child will be clinically well.

In infants with a functioning VSG shunt the child will be well, the fontanelle is soft, the cranial sutures are not splayed, and the head circumference should follow rather than cross the centiles. A functioning shunt will create a full, even tense subgaleal pocket; this is normal and indicates the shunt is working.

The majority of infants who have a VAD or VSGS inserted will go on to require permanent CSF diversion, normally with a VP shunt in the first instance. During the postoperative course, the OFC should be monitored and plotted against normal values and the child should be observed for signs of symptomatic hydrocephalus. The subgaleal pocket can be tapped percutaneously if additional CSF drainage is required. Once the child is over term-corrected age and above 2.5 kg they can be considered for a VP shunt if they remain symptomatic. A small proportion of children do not require permanent CSF diversion and can simply be monitored clinically in the outpatient setting. In those patients who do not need further surgery for CSF diversion we remove their subgaleal shunts as an elective procedure at around 2 months corrected age.

Assessment and management of term infants and children with hydrocephalus

Deciding when treatment is indicated

The diagnosis of hydrocephalus can be easy if children present acutely with the classic symptoms and signs of raised intracranial pressure and with ventriculomegaly present on imaging. In such cases the decision to proceed with treatment is straightforward. However, in some cases where there is 'compensated hydrocephalus' the decision to treat can be more difficult, it is not unusual for paediatric neurosurgeons to see relatively well children in clinic who have been found to have ventriculomegaly on imaging. Some patients may have subtle cognitive impairment, behavioural difficulties, or poor school performance, and the decision to intervene can be difficult. Some are seen when they are very young and cognitive impairment may be difficult to detect. Some authors believe that asymptomatic mild or moderate ventriculomegaly does not require treatment (Kalra and Kestle, 2015), but others express concern that children may not reach their developmental potential if they have untreated hydrocephalus. In such cases management strategies include serial imaging to assess for increasing ventricular size and sometimes a period of intracranial pressure monitoring is used to guide the need for intervention.

Radiological ventriculomegaly can be due to hydrocephalus or atrophy of the surrounding brain tissue. The differentiation between these conditions can be difficult. The imaging characteristics that suggest hydrocephalus rather than atrophy include enlargement of the recesses of the third ventricle, dilatation of the temporal horns, periventricular interstitial oedema, and effacement of cortical sulci (Dinçer and Özek, 2011).

Surgical options in the treatment of paediatric hydrocephalus

Since the 1890s the treatment for hydrocephalus has been surgical. In the early twentieth century Dandy and others explored extripication of the choroid plexus and attempted to bypass obstructed CSF pathways using an open craniotomy. This was initially performed through a subfrontal approach and open third ventriculostomy was performed. These early procedures carried high rates of operative morbidity and mortality (10–20%) (Warf, 2014).

CSF shunts

Sixty years ago, silastic tubing and valves were introduced, and surgical treatments shifted towards the diversion of CSF with shunts. Since then most anatomical cavities have been utilized as potential reservoirs or conduits for CSF drainage, CSF shunting has become the standard treatment for hydrocephalus. The commonest type of shunt in use today is the ventriculoperitoneal shunt but other sites are sometimes used, such as the right atrium of the heart (VA shunt) or the pleural cavity. While the introduction of shunts has made a dramatic impact on a previously devastating disease, the complications related to shunts can plague children with hydrocephalus.

External ventricular drains (EVDs) are commonly used for temporary CSF diversion, for example in the presence of infection or haemorrhage, until permanent CSF diversion can be instituted.

Endoscopic third ventriculostomy

In the 1990s improvements in endoscope design led to the development of neuroendoscopic procedures for the treatment of hydrocephalus. Endoscopic third ventriculostomy (ETV) involves the introduction of an endoscope into the frontal horn of the lateral ventricle, through the foramen of Munroe and into the third ventricle. An opening is then made in the floor of the third ventricle under direct vision. This allows CSF to pass into the prepontine cistern bypassing distal obstructions in the CSF pathways (ETV is described in Chapter 93). This technique is now routinely performed in most paediatric neurosurgical centres in high-income countries and allows some patients to be treated without the need for a shunt. ETV is also being used for patients who have previously been treated with a shunt who present with shunt failure (Chhun et al., 2015).

ETV and choroid plexus coagulation

Recently there has been renewed interest in choroid plexus coagulation (CPC) and this has been performed in combination with ETV (Warf, 2005). The technique is performed through a unilateral frontal burr hole using a flexible endoscope. An ETV is performed and then the endoscope is manipulated within the ipsilateral lateral ventricle and the choroid plexus is extensively coagulated along its entire length into the temporal horn. A septum pellucidotomy is then performed, the endoscope is introduced into the opposite lateral ventricle and coagulation of the choroid is repeated on the other side (Warf, 2005). ETV and CPC have predominantly been performed in sub-Saharan Africa but after seeing promising results there are groups in the developed world that are using the technique.

Compared with ETV alone, ETV and CPC has been reported to provide better results in infants (Warf, 2005) and has been shown to be effective in hydrocephalus due to many different aetiologies including aqueduct stenosis and neural tube defects (Warf, 2011; Warf et al., 2012). It appears that the efficacy of this procedure is proportional to the amount of choroid plexus coagulated (Warf et al., 2010). Due to its proximity to critical structures, some surgeons are concerned about the potential long-term effects of coagulation of the choroid plexus. As for many treatments of hydrocephalus knowledge of the effect on neurocognitive outcome is limited although there is some short-term data that shows that the technique has similar cognitive outcomes to VP shunting (Warf et al., 2009).

Selection of the most appropriate treatment modality

Once the diagnosis of hydrocephalus has been made treatment needs to be planned. The clinical urgency of the situation may dictate the extent of any preoperative imaging that has been performed but in the majority of cases in high-income countries it is possible to perform an MRI scan before the need for the first surgical intervention.

Careful analysis of the MRI scan usually enables an assessment of the cause of the hydrocephalus, and specifically the location of any potential obstruction to CSF flow. The presence of a mass lesion (tumour, abscess, cyst, and others) is readily identified on MRI scan and it is possible that removing the mass lesion itself may resolve the hydrocephalus.

With the increased use of endoscopic techniques appraisal of the imaging is critically important. If a point of obstruction is identified it may be possible to bypass the obstruction using an endoscopic technique, thus avoiding a shunt. Many paediatric neurosurgeons consider this to be preferable due to the long-term implications of maintenance and complications associated with shunts.

The choice between ETV and shunts is controversial and there are currently no completed randomized controlled trials that compare the two treatment options. When ETV and shunts are compared this is normally done by comparing the failure rates of each procedure, which is the time until further surgery is performed. In unselected cohorts the failure rates of ETV at 2 years is about 35% (Kulkarni et al., 2010a; Kahle et al., 2015). Prognostic factors include patient age and the aetiology of the hydrocephalus. These are included in the ETV success score which is a useful, validated tool that allows an estimation of the potential success rates of ETV in different patients (**Table 89.2**) (Kulkarni et al., 2010b). Our approach to a patient with symptomatic hydrocephalus is summarized in **Figure 89.4**.

To calculate the endoscopic third ventriculostomy success score (ETVSS), add the three component scores to get a percentage chance of an ETV being successful.

All patients should have volume imaging, normally MRI, for use with neuronavigation. Preterm infants under 2 kg are treated with ventriculosubgaleal shunts. In term infants and children where an obstruction is identified on preoperative imaging and the anatomy appears favourable for an endoscopic procedure we consider ETV.

Table 89.2 Calculation of the ETVSS score

Age	Score
<1 month	0
1–6 months	10
6–12 months	30
1–9 years	40
10 years or more	50
Aetiology	**Score**
Infection	0
Myelomengocele	20
IVH	20
Non-tectal brain tumour	20
Aqueduct stenosis	30
Tectal tumour	30
Other	30
Previous shunt	**Score**
Previous shunt	0
No previous shunt	10

Source data from Kulkarni, A.V. et al. Predicting who will benefit from endoscopic third ventriculostomy compared with shunt insertion in childhood hydrocephalus using the ETV Success Score. *J. Neurosurg. Pediatr.* 6, 310–15 (2010).

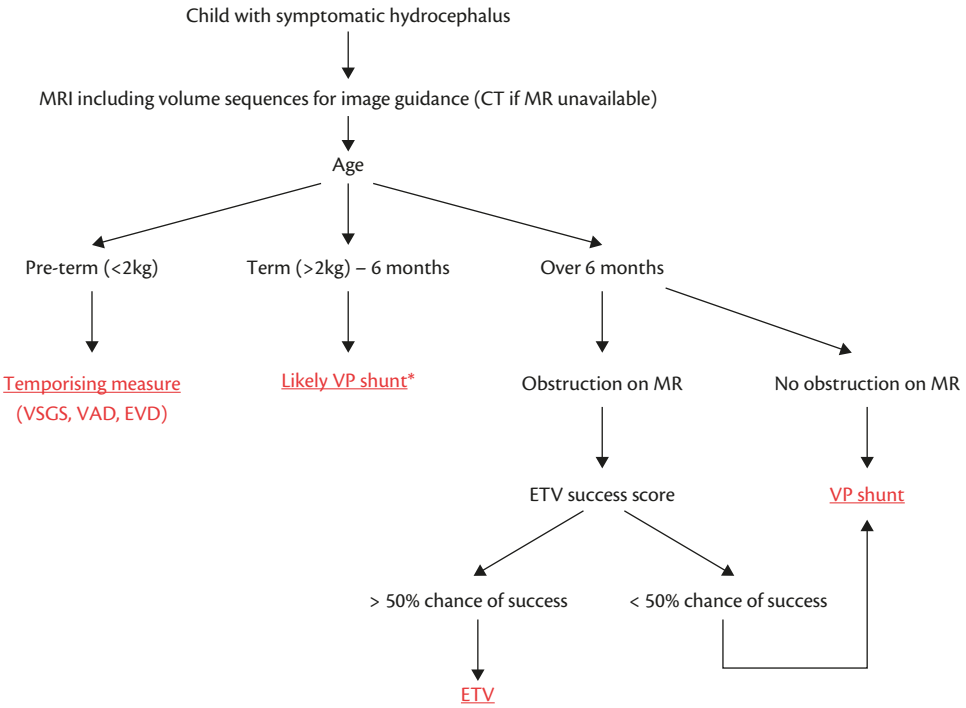

Fig. 89.4 Treatment algorithm for the management of symptomatic hydrocephalus.

Term infants over 2 kg but under 6 months of age are normally treated with a VP shunt due to the poor success rate of ETV in this age group but in some circumstances for example where children have intra-abdominal comorbidities or cranial arachnoid cysts ETV may be offered.

In those over 6 months, if evidence of obstruction is present on MR we perform an ETV success score and if the chances of success are greater than 50% ETV is performed as a primary treatment. In those where there are no obstructive features on MR or when the chance of ETV success is less than 50%, a shunt would be performed in the majority of cases. If patients represent with shunt failure in the future then ETV would be reconsidered.

Inserting a ventriculoperitoneal shunt

VP shunt insertion has one of the highest failure rates of any neurosurgical procedure and should be performed by a trained and efficient team. When a shunt actuarial survival curve is examined up to 20% of shunts are seen to fail in the first 6 months. Early shunt failures are predominantly due to infection, occlusion of catheters through suboptimal placement or migration of the shunt components secondary to disconnection. Surgeons have the opportunity to reduce the incidence of these early shunt failures, but shunt surgery is unforgiving of technical errors.

Figure 89.5, which accompanies the following description, is of a VP shunt insertion in a neonate but the steps of the procedure are similar for shunts in children of all ages. Shunt surgery should be performed by an appropriately trained team, shunts should ideally be the first case of the day and to minimize the infection risk movement around, in, and out of the operating theatre by personnel should be kept to an absolute minimum. We place signs on the doors of the operating theatre and apart from the emergency exits keep theatre doors locked (Fig. 89.5C). Current National Institute of Clinical Excellence (NICE) guidelines recommend that patients are showered or bathed with soap prior to surgery. Many studies have looked at the effectiveness of chlorhexidine-based body washes in reducing surgical site infection, currently effectiveness in reducing surgical site infection (SSI) is uncertain, although studies have demonstrated a reduction in bacterial skin levels (National Collaborating Centre for Women's and Children's Health, 2008). We treat all patients with chlorhexidine body wash and shampoo the day before and the morning of surgery and have found that since introduction of this, we have significantly reduced our surgical site infection rates.

Under general anaesthesia with endotracheal intubation and the tube directed to the contralateral side to the shunt, the patient is positioned supine on the operating table with the head supported on a jelly head ring for infants or the Mayfield horseshoe headrest for children over 2 years old. The head is turned towards the contralateral side and a roll is placed under the shoulder so that the chest wall is raised and there is a straight trajectory from the cranial incision to the abdominal incision to facilitate tunnelling (Fig. 89.5A). In neonates and infants it is often necessary to use a large chest roll to elevate the chest due to the large head size relative to the body in this age group. Patient normothermia is important, especially in neonates and infants (National Collaborating Centre for Women's and Children's Health, 2008) and we routinely use warm air flow mattresses to assist with this (Fig. 89.5A).

Intravenous antibiotics are given on induction as they reduce surgical site (National Collaborating Centre for Women's and Children's Health, 2008) and VP shunt infections (Klimo et al., 2014). A small amount of hair may be clipped at the incision sites to aid quality of closure although hair removal has not been shown to decrease the risk of infection (National Collaborating Centre for Women's and

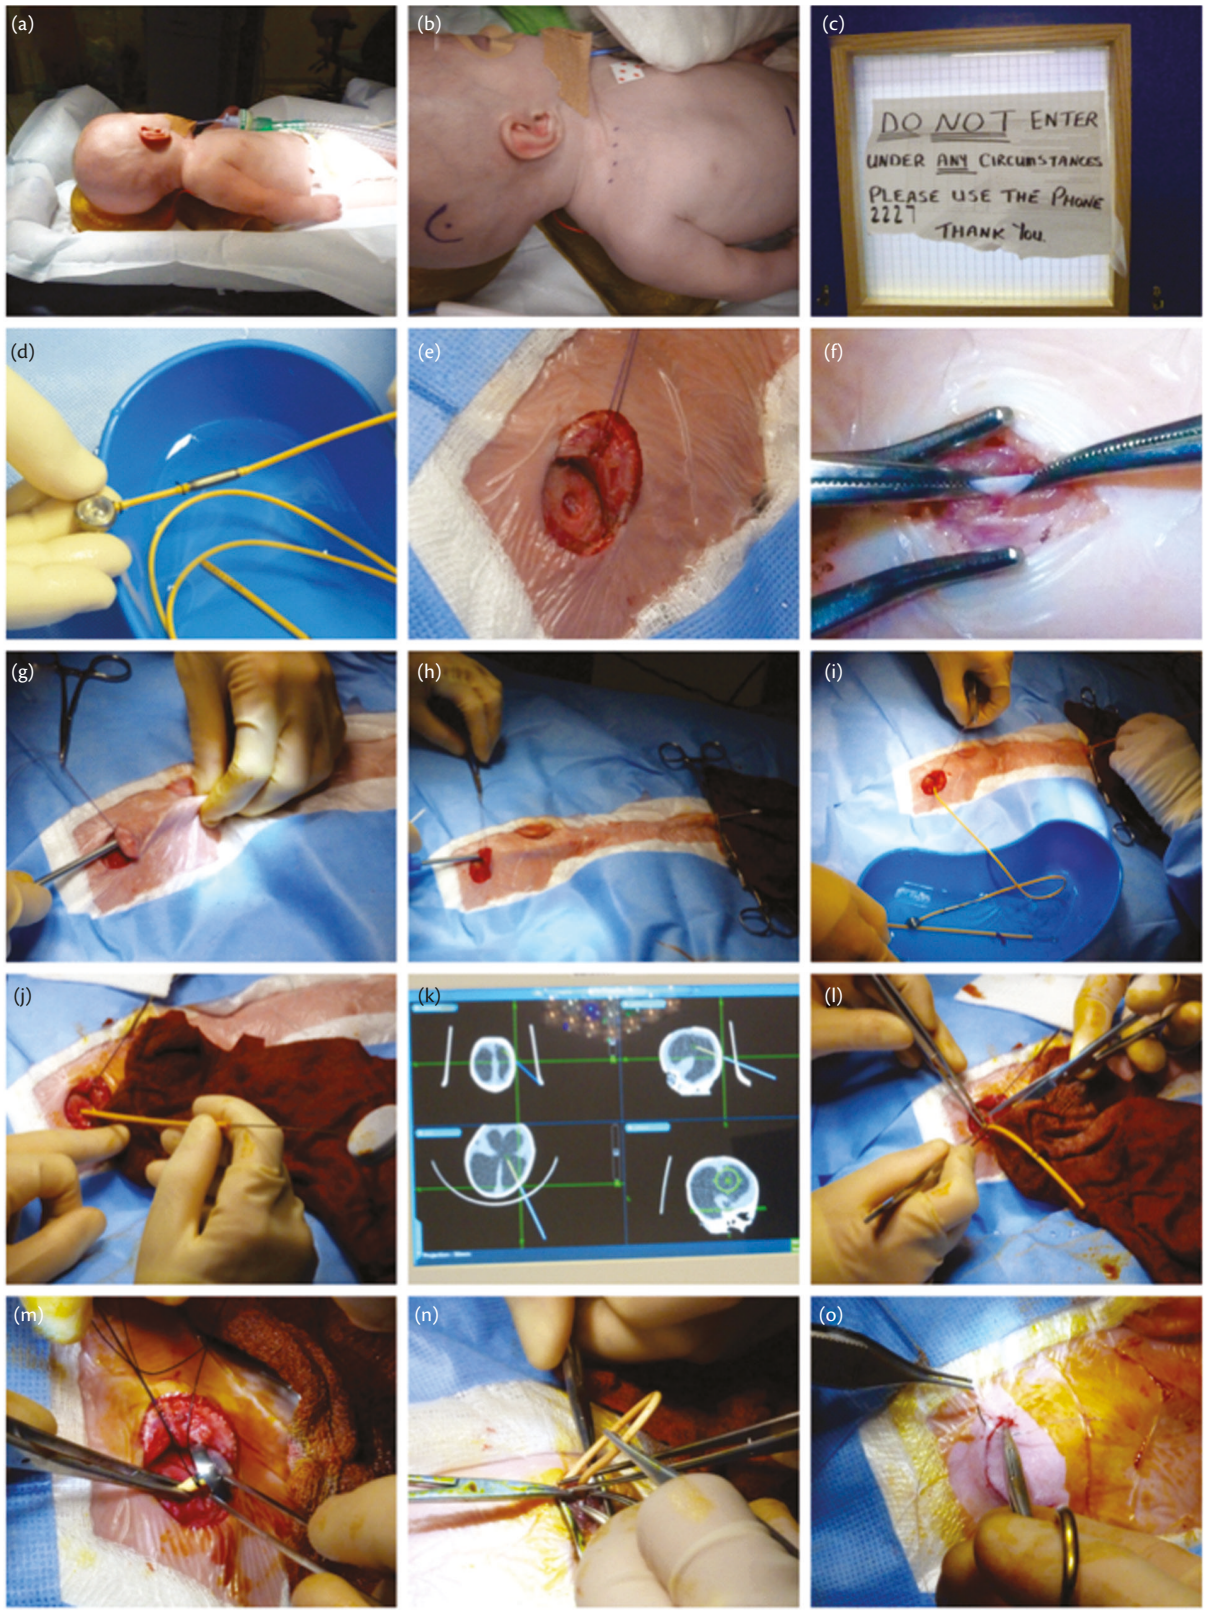

Fig. 89.5 Insertion of a ventriculoperitoneal shunt.

Children's Health, 2008). Frontal and parieto-occipital burr holes are the most commonly used entry sites for the ventricular catheter. Either route is acceptable and a recent systematic review found no evidence to recommend one route over the other (Kemp et al., 2014). Frontal burr holes are normally placed 2–3 cm off the midline 1 cm anterior to the coronal suture, parieto-occipital burr holes are placed 2–3 cm above and 2–3 cm posterior to the pinna, although if image guidance is used these entry points may vary based on the

patient's preoperative imaging. The preoperative imaging should be studied as some children with posterior fossa cysts or other malformations have transverse sinuses that are located much higher than usual, in which case a parieto-occipital entry point must be planned and adjusted accordingly. Cranial and abdominal skin incisions are marked (**Fig. 89.5B**).

The skin is meticulously prepared with an appropriate skin prep. We use a chlorhexidine-based solution in all age groups. The boundaries of the operative field are defined by large sterile swabs and an opsite cover is used to hold these in place. The surgical drapes are then attached to the swab and opsite construct, so the adhesive is not attached directly to the patient's skin. The shunt is assembled on a separate trolley to that used by the scrub nurse (**Fig. 89.5D**). There is currently no evidence that one valve design is superior to another (Baird et al., 2014). We use a low-profile fixed pressure valve as our standard valve (Miethke Paedigav) and reserve programmable valves for complex cases. Chapter 93 gives more information on valve design.

The skin incisions are opened. We score the skin with a scalpel blade and then deepen the incision through the galea with monopolar diathermy to minimize blood loss. Skin incisions should be shaped so that there is no shunt hardware immediately beneath the incision to minimize the risk of skin breakdown leading to the shunt becoming exposed. A high-speed drill is used to produce a small burr hole (**Fig. 89.5E**). The abdomen is opened simultaneously by an assistant. Various entry points in to the abdomen are described. We use a linear incision off the midline between the umbilicus and the costal margin. Dissection is taken down to the anterior rectus sheath that is opened. The fibres of the rectus muscle are split and the posterior rectus sheath and peritoneum are picked up with clips (**Fig. 89.5F**). This layer is then divided and entry to the peritoneal cavity is confirmed by the passage of a blunt instrument in to the cavity or through direct visualization of omentum or bowel.

A shunt passer is then tunnelled through the subcutaneous fat from one incision to the other (**Figs. 89.5G** and **89.5H**). Great care must be taken to ensure that the tunnelling is not taken too deep as either the chest cavity or posterior fossa can be entered. If too superficial a skin laceration can occur. A release incision is sometimes necessary in the neck if significant resistance is felt. If tunnelling to a frontal burr hole an incision behind the ear is required and tunnelling is performed in two steps. The peritoneal tubing is then passed down the shunt tunneller and the tunneller is removed from one of the incisions (**Fig. 89.5I**). The tubing is pulled and the distal end coiled in a swab soaked in aqueous betadine solution. The valve (and reservoir if used) are wrapped in a swab soaked in aqueous betadine at the cranial end while the ventricular catheter is sited.

There is evidence that ventricular catheters with resting places away from the ventricular wall and choroid plexus have a lower tendency to block and most surgeons will have experience of ventricular catheters located in suboptimal locations. Various technical adjuncts are described to improve the position of ventricular catheter placement in an attempt to improve the longevity of VP shunts including intraoperative ultrasound (Whitehead et al., 2007) and frameless stereotaxy with electromagnetic (EM) or optical guidance systems. Endoscopic placement of ventricular catheters has not been shown to improve shunt longevity (Kestle et al., 2003; Kestle, 2010). We use EM guidance for the majority of ventricular catheter placements as it improves the position of ventricular catheters (Hayhurst et al., 2010; Levitt et al., 2012) and may therefore improve shunt longevity (Hayhurst et al., 2010). For this the stylet is removed from the ventricular catheter and is replaced with the EM stylet. A small dural opening is made with a scalpel and the cortical surface is diathermized. The ventricular catheter is aligned using a navigation system (**Figs. 89.5J** and **89.5K**) and inserted along the trajectory. A 'pop' is usually felt as the catheter enters the ventricle and entry is confirmed by the free passage of CSF from the catheter. A sample of CSF is routinely taken for microbiological analysis. The ventricular catheter is then cut to a length that has been predetermined based on the preoperative imaging (**Fig. 89.5L**), and the catheter is connected to the reservoir or valve. We use a reservoir with a right-angle connection, alternatively a right-angle guide can be used with an in-line valve. It is also acceptable to simply bend the catheter, but it should be noted that in children with a thin cortical mantle the catheter may move so that it reaches an almost vertical orientation. The valve is then seated within its subgaleal pocket by gentle traction on the distal catheter from below and the ventricular catheter is secured to the reservoir with a silk tie (**Fig. 89.5M**). CSF is confirmed to be dripping from the distal tubing before the distal catheter is placed into the peritoneal cavity.

Accurate skin closure is critical as any leakage of CSF can lead to infection and increases the risk of skin breakdown. The galea and skin are closed separately. We use an absorbable suture for both. Likewise, the anterior rectus sheath and abdominal skin incision are closed with absorbable sutures. Dressings are then applied and left *in situ* for 48 hours.

In uncomplicated cases patients are observed for a period of 2–3 days before being discharged home. We do not use postoperative antibiotics routinely. If wounds require cleaning before 48 hours post-op this is performed with sterile saline. After 48 hours patients are advised to keep the wounds clean and can shower if they wish in accordance with the current NICE guidelines on surgical site infection (National Collaborating Centre for Women's and Children's Health, 2008). We see patients to check on the status of the wounds within two weeks. Outpatient follow-up is performed within 2 months along with a postoperative scan to assess the position of the ventricular catheter and the size of the ventricles. We also perform a scan between 12 and 18 months to serve as a baseline for future reference as data from the shunt design trial showed that ventricular size continues to decrease after 3 months, but stabilizes by about 14 months (Drake et al., 1998). The early postoperative scan is valuable, however, due to the high rates of shunt failure within the first year. Patients are then followed up on an outpatient basis for life, initially every 6 months, then annually, and in some cases, every two years. We do not routinely repeat imaging outside these schedules unless patients develop symptoms.

Complications of VP shunts

Parenchymal haemorrhage related to ventricular catheter insertion is reported to occur in between 1 and 4% of catheter placements (Savitz and Bobroff, 1999; Kalra and Kestle, 2015). Most of these haemorrhages are asymptomatic (Savitz and Bobroff, 1999) but they have potential to cause neurological deficit, depending upon the location of the haemorrhage.

Injury to abdominal or thoracic organs can occur during placement of a VP shunt. Shunt tubing has been reported to erode through

visceral walls, perforations of the stomach, small and large bowel, bladder, and uterus have all been reported (Wong et al., 2012).

VP shunts have high failure rates with 40% of children requiring further intervention in the first 2 years after their first shunt insertion (Kulkarni et al., 2013; Kahle et al., 2015). The majority of these failures are due to shunt obstruction. Other causes of failure are infection, disconnection, migration, fracture, and overdrainage. Failure rates are higher in younger children with patients under 2 years being at highest risk (Kalra and Kestle, 2015).

The commonest site for shunt obstruction is the ventricular catheter, accounting for 63% of cases of obstruction in one study (Di Rocco et al., 1994) although the shunt can block anywhere along its length. Proximal catheter blockages are most commonly due to the presence of choroid plexus within the ventricular catheter lumen. Valve blockages tend to occur very early after shunt insertion or revision and this is likely to be due to debris or blood from surgery (Kalra and Kestle, 2015). Patients with VP shunt failure often present with symptoms of raised ICP and imaging that demonstrates increasing ventricular size. Shunt obstruction is treated with urgent surgery to replace the blocked component. In some patients shunt failure is more subtle and a period of ICP monitoring may be indicated prior to shunt revision.

Patients who experience shunt infection have approximately twice the risk of death and undergo three times the number of shunt-related procedures as those who do not develop infection (Schoenbaum et al., 1975; Wong et al., 2012). Mortality from shunt infection is in the region of 10% and in the long term those who have suffered this complication have poorer outcomes in terms of cognition and school performance (Vinchon and Dhellemmes, 2006). Shunt infection occurs in between 3% and 12% of shunt procedures and most cases occur within 3 months of surgery (Kulkarni et al., 2001). Symptoms include pyrexia, malaise, and irritability, redness over the shunt hardware and headache. A shunt tap can confirm the diagnosis. Positive CSF analysis shows a raised white cell count with organisms seen on microscopy, and positive CSF cultures. Less commonly shunt infection can present with an abdominal pseudocyst with symptoms of shunt malfunction and abdominal pain.

The commonest pathogens in shunt infection are skin commensal organisms such as coagulase negative *Staphylococcus* and *S. aureus* species (Thompson and Hartley, 2014; Kahle et al., 2015). Infection can occur when a shunt, the CSF, or the wound becomes contaminated and this may occur at the time of surgery, through the wound in the immediate postoperative period or through direct contiguous spread such as in abdominal infection (Thompson and Hartley, 2014). If shunt infection is confirmed the majority of neurosurgeons remove the affected shunt hardware and insert an EVD. Patients are treated with intravenous and sometimes intrathecal antibiotics until the CSF is sterile at which time the shunt may be internalized or an endoscopic procedure may be considered.

Shunt overdrainage can present acutely with extra-axial fluid collections, or chronically as the slit ventricle syndrome. As the ventricles reduce in size following VP shunt insertion extra-axial fluid or blood can accumulate. This is more common in older children who have large ventricles. Programmable valves, set to a high resistance may be used to treat this or in high risk cases, to prevent it occurring. If extra-axial collections do develop management can be difficult. Strategies involve reducing the overdrainage and sometimes draining the extra-axial collections. Valve replacement with a valve with a higher opening pressure or insertion of an antisyphon device can be performed. Once the overdrainage has been reduced consideration can be given to draining the extra-axial collections through an appropriately positioned burr hole.

Slit ventricle syndrome

Headaches are common in children with VP shunts. Some children develop very small ventricles following VP shunt insertion and in association with headaches may be labelled as having slit ventricle syndrome. There is no consistent, precise definition of the syndrome in the literature but typically these children have had a shunt for several years and their ventricles have become very small (Kalra and Kestle, 2015). Slit ventricle syndrome is caused by a chronically overdraining shunt, where the skull is too small for the brain. Brain compliance is reduced and therefore raised CSF pressure does not cause ventricular dilatation.

Children may present with symptoms of chronic low-pressure headaches, or with cyclical headaches suggestive of raised intracranial pressure. Options for treating these patients are controversial and include intracranial pressure monitoring, revising the shunt or changing to a programmable or flow regulated valve, and cranial vault expansion using subtemporal decompression (Kahle et al., 2015).

Long-term outcomes for children with hydrocephalus

Most children who are treated with shunts require shunt revision at some point in their lives. One long-term study found that 32% of patients required between one and three shunt revisions, and a further 52% required four or more revisions. Some 29% of patients reported either one or two shunt infections. Up to 70% of patients reported symptoms of depression and up to 45% needed treatment. The majority of adult patients were single and only a quarter of female patients reported having children. Up to 40% of adult patients were dependent with respect to living arrangements (Gupta et al., 2007).

Cognitive outcomes in patients with hydrocephalus are predominantly dependent on the cause of the hydrocephalus and any associated brain abnormalities or primary brain injury. For example, children with isolated aqueduct stenosis have near normal cognitive profiles (Kahle et al., 2015), whereas patients with IVH of prematurity have much higher rates of impairment. Reduced intelligence, learning, memory, and executive functioning can be present (Kahle et al., 2015). Epilepsy is common and has a significant impact on quality of life for patients and their families.

Paediatric neurovascular disorders

Helen G. McCullagh, Tufail Patankar, Tony Goddard, and Atul Tyagi

Introduction

The spectrum of paediatric neurovascular disorders includes several conditions like AVM, aneurysm, and cavernous malformations that occur in adults. Despite the similarity in pathology there are differences in presentation, location, and management of vascular disorders in children as compared to adults. There are disorders that are peculiar to the paediatric population like vein of Galen malformations or intraventricular haemorrhage in premature infants and others that occur predominantly in children though are seen in adults such as the Moyamoya disease.

Recent advances in endovascular therapy, radiosurgery, and multimodality management of vascular lesions have increased the options available to manage these lesions in children.

Identification of underlying gene abnormalities in cavernomas and Moyamoya disease promises to shed new light on the pathogenesis of these disorders. The common neurovascular disorders seen in the paediatric population are discussed in this chapter with the focus on those seen predominantly in children.

Intraventricular haemorrhage in preterm infants

Spontaneous intraventricular haemorrhage is a major complication of preterm birth. Large haemorrhages are associated with a high risk of disability and hydrocephalus

Aetiology

In premature infants, the site of origin of the bleeding is the subependymal germinal matrix, which is located between the caudate nucleus and the thalamus at the level of the foramen of Monro. Vessels in this region occupy border zones between cerebral arteries and the collecting zone of the deep cerebral veins and have increased permeability or germinal matrix fragility when subjected to hypoxia and or increased venous pressure, relating to changes in cerebral blood flow (CBF). Fluctuations in CBF in the preterm are associated with IVH, particularly as preterm infants have impaired autoregulation of CBF compared to term infants. Risk factors for IVH include the causes of changes in blood pressure for example during rapid infusion of fluid boluses, increases in cerebral venous pressure during labour and delivery caused by compression of the fetal head and tracheal suctioning. Causes of rapid fluctuations in CBF include hypercarbia, asphyxia, acidosis, and hypoglycaemia. Coagulation abnormalities often seen after prolonged intrapartum asphyxia and resuscitation are contributing factors also.

In term neonates IVH usually results from choroid plexus haemorrhage, deep venous sinus thrombosis, and thalamic infarction. The most common clinical symptoms are seizures and poor feeding.

Incidence

The incidence of IVH in very low birth weight infants (<1500 g) declined from 40% to 50% in the early 1980s to 20% by the late 1980s. However, in the last two decades the occurrence of IVH has remained static. In extremely premature infants weighing 500–750 g, IVH occurs in about 45% of neonates (Ballabh, 2010).

Presentation

IVH almost always occurs in the first five postnatal days with 50% occurring on the first day of life. In one study, IVH was detected in 20% within the first hour of age in babies with birth weight less than 1750 g subjected to serial cranial ultrasounds commencing minutes after birth. In the same study the overall incidence of IVH was similar between vaginal and Caesarean deliveries (Shaver et al., 1992).

Presentation is often silent with 25–50% of IVH found on routine cranial ultrasound examination of the preterm neonate. However, presentation may be with a catastrophic syndrome of rapid neurological deterioration evolving over minutes to hours with coma, flaccid tone, tonic posturing, or neonatal seizures and absence of spontaneous movements. The most common presentation is that of a subacute deterioration in alertness and spontaneous movements over hours to days often with hypotonia. Respiration may be affected.

Routine cranial ultrasound screening should be performed on all babies born with a gestational age less than 32 + 6 weeks or with a birth weight of 1.5 kg or below. In the United Kingdom, the neonatal networks suggest screening on days 0–3, repeated on days 3–5, 7–10, at 28 days and again at 36 weeks corrected gestational age or just prior to discharge from the unit for babies born between 23 and 27 + 6 weeks. Babies of any gestation who are ventilated should have routine screening scans on a weekly basis and again at discharge (Periman and Rollins, 2000).

Table 90.1 Severity and grading of IVH

Grade I	Germinal matrix only
Grade II	IVH filling 10–50% of the ventricle
Grade III	IVH filling more than 50% of the ventricle
Grade IV Periventricular haemorrhagic infarction (PVHI)	Haemorrhage in any parenchymal location in addition to a unilateral or bilateral IVH PVHI is a more precise pathophysiological definition

Reproduced with permission from Lu-Ann Papile, Jerome Burstein, Rochelle Burstein, Herbert Koffler, Incidence and evolution of subependymal and intraventricular hemorrhage: A study of infants with birth weights less than 1,500 gm, *The Journal of Pediatrics*, Volume 92, Issue 4, pp. 529–34, Copyright © 1978 Elsevier.

Grade I IVH corresponds to mild, grade II moderate, and grades III and IV severe IVH (Table 90.1). Each grade of IVH may be unilateral or bilateral with either symmetrical or asymmetrical grades of IVH.

Management

The optimal clinical management of IVH and posthaemorrhagic ventricular dilatation remains unclear. A common approach involves temporary treatment of hydrocephalus in these patients with a ventriculosubgaleal shunt (VSGS), ventricular access device (VAD), or external ventricular drain (EVD) until it becomes evident that the patient needs and can tolerate permanent CSF diversion. In a systematic review and meta-analysis of outcomes and complications, the range of outcomes was similar for VSGS, VAD, and EVD (Badhiwala et al., 2015). Posthaemorrhagic hydrocephalus (PHH) is considered in detail in Chapter 89.

Prognosis

Mortality and short-term morbidity (grades I and II) mortality of intraventricular haemorrhage. For mild IVH (grades I and II) mortality is 5% with only 7% of survivors exhibiting PHH (Murphy et al., 2002). In severe IVH (grade III and periventricular haemorrhagic infarction [PVHI]) the mortality rate is approximately 20% and 75% of survivors develop PHH. Severe IVH also increases the risk of periventricular leukomalacia (PVL) (Kusters et al., 2009)

The long-term outcome of infants with IVH who survive worsens with increasing severity of IVH and decreasing gestational age. In a prospective population-based cohort study of 1812 infants born before 33 weeks gestation the prevalence of cerebral palsy at 5 years of age increased with severity of IVH. CP was diagnosed at 5 years of age in 8% of children with grade I IVH, 11% in grade II,19% in grade III and 50% in grade IV (Beaino et al., 2010). Infants with isolated grade I–II IVH also had a higher risk of neurosensory impairment (Bolisetty et al., 2014). However, in a large longitudinal observational study in 16 centres of 1472 infants born at less than 27 weeks gestation, by follow-up at 18–22 months the neurodevelopmental outcomes of extremely low gestational age infants with grade I or II IVH were not significantly different from those without haemorrhage (Payne et al., 2013).

Controversies

There is no role for the routine use of serial lumbar punctures to reduce the need for shunt placement or to avoid progression of hydrocephalus in preterm infants

Intraventricular thrombolytic agents including tissue plasminogen activator (tPA), urokinase or streptokinase are not recommended as methods to reduce the need for shunt placement in premature infants with PHH. In one study using DRIFT (Drainage, Irrigation and Fibrinolytic Therapy) DRIFT was associated with an increased risk of secondary IVH (Whitelaw et al., 2007).

Several postnatal pharmacological prevention strategies for IVH have been studied. There is no evidence that the use of phenobarbital, indomethacin, or vitamin E confer overall benefit in terms of neurodevelopmental outcome.

Vein of Galen malformations (VGAM)

Introduction

VGAMs are rare congenital midline vascular abnormalities in the region of the cavum veli interpositi (velum interpositum). The primary pathology is considered to be an abnormal connection between the choroidal arteries and the median prosencephalic vein such that the flow through the fistula prevents normal regression of the median prosencephalic vein. These abnormalities account for 1% of the arteriovenous malformations and around 30% of the vascular malformation in the paediatric population.

Clinical presentation

VGAMs can present antenatally, in early infancy, or in childhood with signs and symptoms ranging from high-output congestive heart failure (CHF) and hydrocephalus to seizures and intracranial haemorrhage.

Imaging

Imaging shows a large midline varix in a neonate or infant within milimetres to several centimetres. The varix can vary from a few centimetres to several centimetres. Often a large varix suggests a venous stenosis and is frequently associated with ventriculomegaly and subcortical white matter calcification from chronic ischaemia. Antenatal diagnosis via ultrasonography and fetal MRI has been associated with improved outcome in survivors.

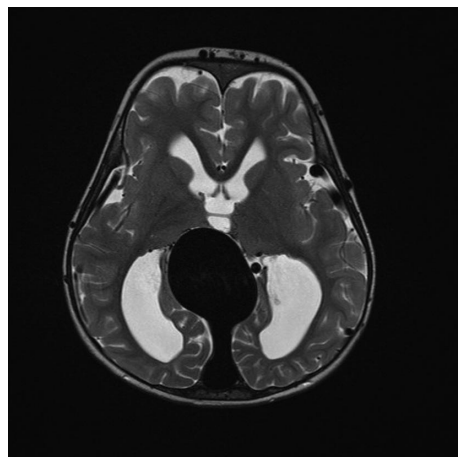

Fig. 90.1 T2 axial MRI scan image showing a venous varix in the quadrigeminal cistern with ventriculomegaly.

Differential diagnosis

VGAM resembles a persistent embryonic falcine sinus draining a single or multiple arteriovenous fistula. VGAMs are categorized based on their angioarchitecture into mural and choroidal. Multiple feeders, including choroidal, thalamoperforating, and pericallosal arteries, often supply choroidal galenic aneurysmal malformations. In contrast, mural VGAMs are often supplied by fewer feeders, including callosal and posterior choroidal arteries. Supply is usually unilateral.

The differential diagnosis for VGAM would include arteriovenous malformation with drainage into the vein of Galen or dural arteriovenous fistula. Vein of Galen aneurysmal dilatations drain into the true vein of Galen. Dural AV fistulas are high flow fistulas and are often supplied by the external carotid artery. Pial AVMs have a true nidus and are rare in children below three years.

Venous obstruction associated with VGAMs can occur at either the level of the falcine sinus or at the base of the skull.

Treatment and prognosis

Untreated vein of Galen malformations have a very poor prognosis. Treatment can be achieved by either the arterial or the venous route. Coils, onyx, and glue have been used to access and treat the fistula. The venous route is often used in patients where the arterial route cannot be approached successfully.

Younger age at first diagnosis, CHF, seizures, and choroidal angioarchitecture are predictive of an adverse clinical outcome. Poor outcomes may also be associated with hydrocephalus at presentation, and incomplete embolization.

The goals of endovascular treatment vary depending on clinical presentation. Neonates with CHF refractory to medical management are treated urgently to establish hemodynamic stability and to allow for heart and brain development. In neonates without CHF, the goal of treatment is to prevent cerebral venous hypertension, white matter damage, and the 'melting brain syndrome'. In these cases, treatment is often deferred until the child is aged 5–6 months to allow for greater cerebral maturation and enlargement of arteries. CSF shunting in VGAM is highly controversial but may be necessary in some patients with progressive ventriculomegaly especially if there are features of raised intracranial pressure.

Results

The overall survival in one series of 26 patients over 19 years was 76.9%. This included five patients who were not treated either because of minimal symptoms or severe comorbidities. Over two-thirds of treated patients had no evidence of developmental delay (Li et al., 2011).

Moyamoya disease/syndrome in childhood

Moyamoya disease (MMD) is a cerebrovascular disease of unknown aetiology characterized initially by bilateral narrowing or occlusion of the terminal internal carotid arteries (ICA) with subsequent involvement of the anterior or middle cerebral arteries. Multiple basal collateral vessels typically develop in response to the reduction in CBF. Suzuki and Takaku made the observation that collateral vessels gave the appearance of a puff of smoke on cerebral angiography and coined the term 'moya moya' in 1969.

Moyamoya syndrome (MMS) describes a similar process with unilateral or bilateral vascular changes that occur in association with conditions like Down syndrome, Neurofibromatosis type I, cranial irradiation, autoimmune disorders, meningitis, and atherosclerosis in adults.

The reduction in CBF can lead to ischaemic episodes in children usually in response to hyperventilation with activities such as crying.

Epidemiology

MMD is found in all ethnic groups but is 10 times more common in East Asian populations as compared to the west. A study conducted in California and Washington State showed that the annual incidence rate of MMD and MMS was 0.086/100 000/year, which is 4–13 times lower than incidence of MMD in Japan (Uchino et al., 2005).

All studies showed a female preponderance with twice as many females as males. Age of MMD onset follows a bimodal distribution with the two peaks between 5 and 10 years of age and during the fourth decade. A family history is noted in 10% to 15% of cases in Japan.

Genetic analysis has identified the RNF213 gene in the 17q25-ter region as an important susceptibility gene for MMD among East Asian populations (Kamada et al., 2011). A polymorphism in c.14576G>A in *RNF213* was identified in 95% of familial patients with MMD and 79% of sporadic cases. *RNF213* was correlated with early onset and severe forms of MMD (Miyatake et al., 2012).

Pathology

The pathology of stenosis in the ICA consists of intima thickened by fibrous tissue and the lamella formed by elastic fibre proliferation. Inflammatory changes are notably absent in the vascular wall. In less than 10% of cases the primary lesion starts unilaterally but becomes bilateral in 75% of cases within 3 years.

The Suzuki classification of the angiographic grades (Suzuki and Takaku, 1969), depicts the progression of vascular changes in MMS/MMD from grade I (narrowing of ICA apex); grade II (appearance of deep collateral vessels); grade III (progression of Moyamoya collateral vessels); grade IV (appearance of transdural collateral vessels from the external carotid artery—ECA); grade V (progression of transdural collateral vessels and reduction of Moyamoya vessels); to grade VI (occlusion of ICA and disappearance of Moyamoya collateral vessels).

Clinical features

The commonest presentation in children is ischaemic events unlike adults where both ischaemic events and intracerebral haemorrhage (ICH) tend to occur.

Ischaemic events may be triggered by hyperventilation due to physical or intellectual activity, dehydration, fever, and crying (Guzmann, 2009). In these patients, cortical vessels are most often maximally dilated at steady state to compensate for chronic cerebral ischaemia. Vasoconstriction in response to carbon dioxide decrease related to hyperventilation results in reduced cerebral perfusion and clinical symptoms.

Patients may present with atypical symptoms like headaches, syncope and involuntary choreiform movements (Smith and Scott, 2012).

Cognitive impairment and decline have been reported in patients without a history of stroke, suggesting that there is a deleterious effect of chronic cerebral hypoxaemia on cognitive functions, but this tended to be greater in children who have had a stroke (Kossorotoff, 2012). Bilateral disease and duration of symptoms are the main factors associated with cognitive deficits.

Intracranial bleeding is rare in children and mainly due to rupture of fragile deep collaterals with deep intraparenchymal (basal ganglia or periventricular deep white matter) or intraventricular haemorrhage. Subarachnoid haemorrhage is rare and sometimes due to the rupture of saccular aneurysms located in the circle of Willis, most often in the vertebrobasilar system.

Investigations

Digital subtraction angiography (DSA) remains the best investigation to identify the condition and visualize collaterals from the ECA (Fig. 90.2). MRI and magnetic resonance angiography (MRA) provide information on cerebral arteries, brain parenchyma, cerebral perfusion, and is being used increasingly in the diagnostic assessment and follow-up of patients (Fig. 90.3).

Fig. 90.2 DSA with common carotid artery injection showing stenosis of the terminal ICA, proximal ACA, and MCA with development of basal collaterals. There is sparing of the external carotid vessels.

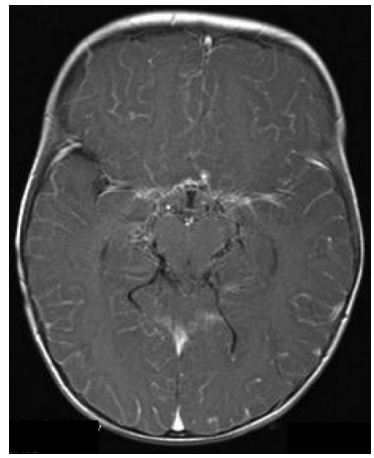

Fig. 90.3 An axial T1 postcontrast image showing the development of numerous basal collateral vessels in the chiasmatic and ambiens cistern.

MRI with MRA may be sufficient to diagnose MMD when the following criteria, which were first established on conventional angiography, are met. MR angiography showing stenosis or occlusion of the terminal portion of the ICA or proximal anterior cerebral artery (ACA) and/or the middle cerebral artery (MCA) (Fig. 90.3). Presence of abnormal vascular networks near the occlusive or stenotic lesions by MR angiography, or MR imaging demonstrating two or more flow voids in the basal ganglia in each hemisphere.

Assessment of cerebral haemodynamics by techniques such as SPECT, PET, xenon-enhanced computed tomography (CT), arterial spin-labelling MR, and CT perfusion may help to identify patients who are at risk of ischaemic events and to direct therapy. The identification of the cerebral hemisphere and region most at risk can help to target surgical revascularization.

Management

The aim of treatment is to increase CBF to the ischaemic cerebral hemisphere and reduce the incidence of ischaemic and haemorrhagic events.

General measures such as avoidance of hypotension, dehydration, and hyperventilation are recommended in order to prevent deterioration of cerebral haemodynamics. Long-term oral antiplatelet therapy, usually aspirin, is started to reduce the incidence of thromboembolic complications.

Surgical options are direct or indirect revascularization. Direct revascularization augments the blood flow by anastomosing an ECA branch to a cortical vessel resulting in an immediate increase in CBF. The most common being superficial temporal artery to a middle cerebral arterial branch (STA—MCA). Indirect revascularization is based on Moyamoya pathophysiology, which spares the ECA and its branches. The tissues supplied by ECA branches is used to augment flow to the ICA circulation over time. The development of cerebral neovascularization from the ECA branches leads to brain revascularization.

Several techniques of indirect revascularization have been developed, all based on a synangiosis procedure. During synangiosis, tissues containing ECA branches (dura mater, temporal muscle, galeal tissue, or the superficial temporal artery) are

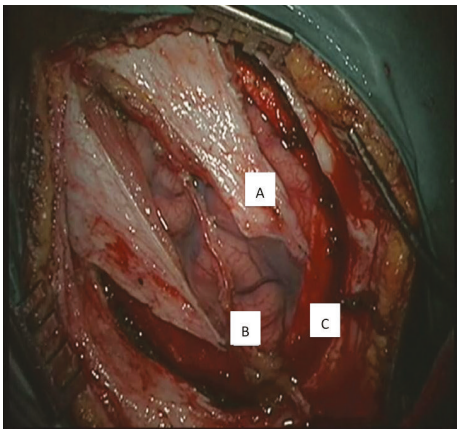

Fig. 90.4 Intraoperative image of an EDAMS procedure: (A) temporalis muscle, (B) superficial temporal artery in continuity, (C) dural margins folded over the cortex.

directly placed in contact with the surface of the ischaemic brain. Development of neovascularization from these tissues is thought to be enhanced by secretion of angiogenic factors from ischaemic brain parenchyma. This procedure does not provide immediate benefit, since efficient neoangiogenesis requires at least 3 months to develop.

Before surgical revascularization, an accurate assessment of vascular status by conventional angiography is required, to avoid disruption of pre-existing collateral vessels developed naturally from the ECA.

The common procedures used to achieve indirect augmentation of flow are encephaloduroarteriosynangiosis (EDAS), encephalodur oarteriomyosynangiosis (EDAMS, Fig. 90.4), and the multiple burr holes procedure (Oliveira et al., 2009). In EDAS the STA is dissected along with a cuff of connective tissue maintaining its continuity. The STA is placed and held on the cortical surface with pial or dural sutures. The temporalis muscle is placed in addition to the STA on the cortical surface with EDAMS.

If multiple burr holes are used, then 10–20 burr holes are made over the affected hemisphere. The dura is opened to allow vascularization from the external carotid circulation.

Results

In a comparison of symptomatic cerebral hemispheres, the 5-year risk of recurrent ipsilateral stroke was significantly greater in medically treated (65%) versus surgically treated (17%) patients. Improving blood flow to the ischaemic cerebral hemispheres could also help to improve cognitive function.

Guzman et al. (2009) reported their series of patients who were both adults and children, treated predominantly by direct surgical bypass. They reported operative morbidity and mortality rates of 3.5% and 0.7% per treated hemisphere, respectively.

Scott et al. (2004) analysed their results in children who underwent indirect revascularization via a modified EDAS technique. The reported operative morbidity was 4% per treated hemisphere.

According to experts' consensus, indirect revascularization is preferred in children because a direct bypass is technically difficult with small-diameter vessels, whereas direct bypass is preferred in adult patients (Roach et al., 2008).

Anaesthetic concerns

Maintenance of haemodynamic stability, normovolaemia, avoiding hypocarbia and hypotension are important if perioperative ischaemic complications are to be avoided.

Prognosis

The natural history of untreated symptomatic MMD in the paediatric population appears to be unfavourable. The course of the disease is variable and could go from rapid progression leading to severe disabilities to clinical silence for several years. Half of the paediatric patients who present with TIA-type symptoms continue to have these types of attacks at a mean follow-up of 7 years (Fukuyama and Umezu, 1985). Untreated MMD is associated with gradual, progressive neurological and cognitive deterioration (Kurokawa et al., 1985).

Intracranial aneurysms

Introduction

Aneurysms in children are extremely rare comprising only 0.5 to 4% of all intracranial aneurysms. In a 1966 study of 6368 ruptured aneurysms, only 41 occurred in children under 19 years of age (Locksley et al., 1966). However, they account for up to 10–15% of haemorrhagic strokes in the first two decades.

Aneurysms

Presentation is heterogeneous, patients present with subarachnoid haemorrhage (32%), headache without SAH (45%), cranial neuropathy (16%), nausea/vomiting (15%), visual symptoms (13%), trauma (13%), and seizures (4%) (Hetts et al., 2009) (Fig. 90.5).

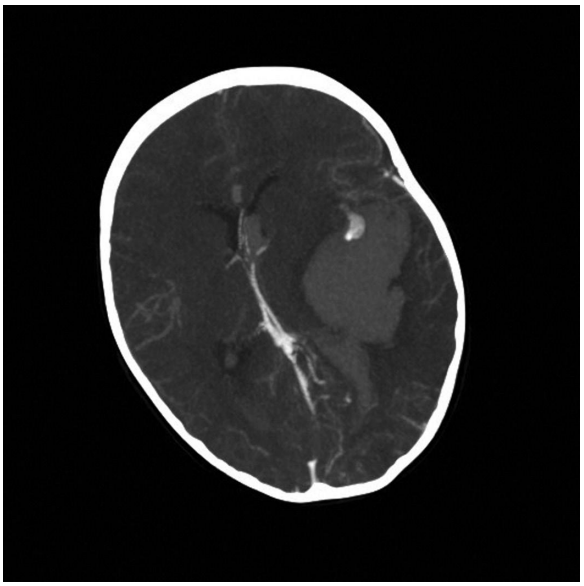

Fig. 90.5 A 27-month-old girl was admitted with sudden onset of headache followed by a drop in the GCS to 6 with a left-sided fixed and dilated pupil. She was transferred intubated and ventilated and underwent a CT and CT angiogram, which shows a left temporal ICH with an aneurysm anterior to the haematoma. A further CT scan showed good evacuation of the haematoma but an evolving infarction in the MCA territory. She had a left decompressive craniectomy which stabilized her condition. On follow-up 2 years later she is walking but has a residual left hemiparesis (arm > leg), her speech is limited to words.

Table 90.2 Lasjaunias paediatric aneurysm classification

1	Fusiform without evidence of infection or trauma
2	Saccular aneurysms without evidence of infection or trauma
3	Infectious (mycotic) aneurysms
4	Traumatic aneurysms

Reproduced with permission from Pierre Lasjaunias, Siddharta Wuppalapati, Hortensia Alvarez et al., Intracranial aneurysms in children aged under 15 years: review of 59 consecutive children with 75 aneurysms, *Child's Nervous System*, Volume 21, Issue 6, pp. 437–50, Copyright © 2005 Springer Nature.

As well as being rare, aneurysms in this population exhibit certain features not seen in the adult population:

They are more often in unusual locations such as the posterior fossa (twice the frequency than is seen in the adult population) and in association with distal vessels. Basilar trunk aneurysms are also more common than terminus aneurysms.

They are more often fusiform and giant, and occur with a slight male predominance. They have a higher rate of multiplicity, especially when associated with vasculopathies and infection (Jordan et al., 2009).

Spontaneous thrombosis has been reported in 5–10% of paediatric ruptured aneurysms but is very rare in adults. Spontaneous recanalization has been reported and thus careful imaging follow-up is required (Lasjaunias et al., 2005; Buis et al., 2006).

Aneurysms in adolescents and teenagers conform more closely to the adult phenotype.

Paediatric aneurysms have been classified into four subtypes by Pierre Lasjaunias (28) (Table 90.2). To this list other authors have added: oncologic aneurysms; haemodynamic aneurysms; and familial aneurysms, which are exceedingly rare.

Aneurysms due to haemodynamic stress may be seen in congenital vascular absence, arteriovenous malformations, and hypertension with or without aortic coarctation.

Traumatic aneurysms are much more common in the paediatric population accounting for 20% of all lesions. They are more common at points of arterial fixation at the skull base or dura with cavernous carotid and pericallosal arteries being the most common. Caroticocavernous fistula may result from cavernous carotid involvement. The majority of traumatic aneurysms even in patients with no underlying arteriopathy have a tendency to enlarge.

From a diagnostic standpoint, there has been a gradual shift towards non-invasive imaging techniques such as MRI and CT angiography with cerebral catheter angiography being reserved for treatment or treatment planning (Figs. 90.6A and 90.6B).

Haemorrhage is twice as common in saccular than in fusiform aneurysms (even in cases of infection) occurring in over 35% of cases. In paediatric patients with pure subarachnoid haemorrhage, aneurysms may be found in up to 57% of patients (Jordan et al., 2009).

A higher proportion of patients with fusiform aneurysms were likely to have an underlying predisposing condition, such as the posterior fossa malformation, haemangiomas, arterial anomalies, cardiac defect, coarctation of the aorta, eye abnormalities, and sternal abnormalities (PHACES) syndrome, tuberose sclerosis, microcephalic osteodysplastic primordial dwarfism type II, Ehlers–Danlos, osteogenesis imperfecta, or neurofibromatosis type 1.

Mycotic aneurysms comprise up to 10% of intracranial aneurysms in the first year of life (Buis et al., 2006) and are more likely to be multiple. Associated underlying conditions to consider are endocarditis, congenital and acquired immunodeficiencies (including AIDS) and meningoencephalitis. New lesions can develop during the course of the acute infection. Aneurysms associated with HIV infection are usually multifocal and morphologically are typically long proximal fusiform lesions.

We have encountered a subset of patients with aneurysms of the distal lenticulostriate arteries in association with trauma. These have been managed with careful observation only, and have a tendency to resolve without rehaemorrhage.

Management of aneurysms in the paediatric population requires a detailed medical history and supplementary investigations that may not normally be required in the adult population such as a sepsis

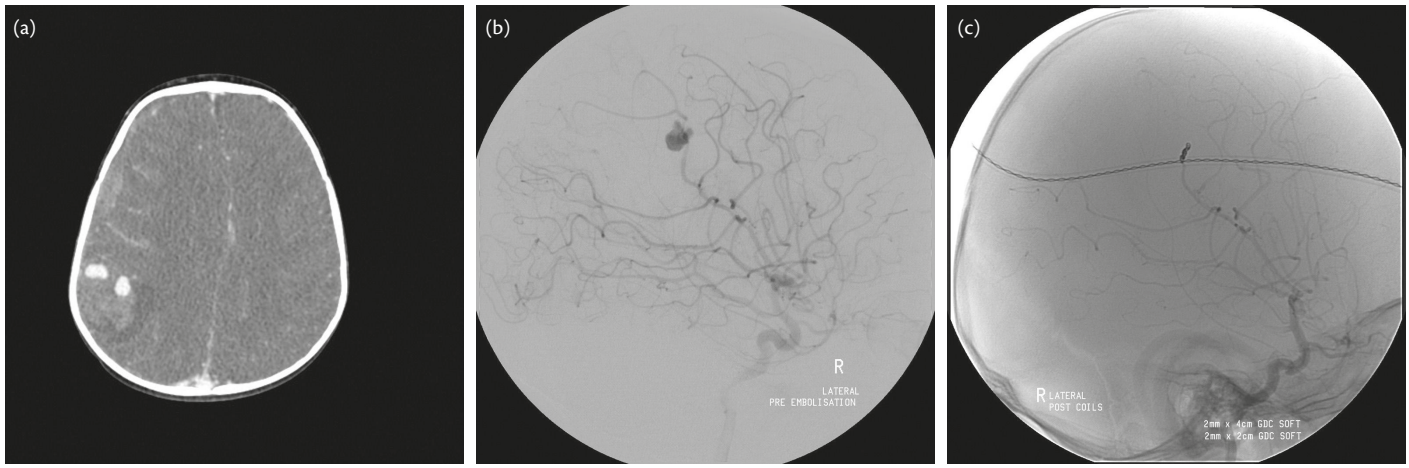

Fig. 90.6 (A) Axial source image of a CT angiogram in a 6-year-old presenting with collapse and seizure. A complex bi-lobed lesion is shown in the right parietal lobe with surrounding parenchymal haemorrhage and a subdural haematoma; (B) A lateral view catheter cerebral angiogram of the right internal carotid artery in the late arterial phase. The complex aneurysm involving a cortical branch is seen; and (C) coil embolization has occurred proximal to the main aneurysm. The microcatheter could not pass a preaneurysm stenosis. There is retrograde filling of cortical branches distal to the occlusion, but no filling of the aneurysm itself.

screen or cardiac structural studies. Additionally, it goes without saying that a multidisciplinary approach is required in all cases, involving cardiologists, paediatric neurologists, neurosurgeons, and interventional neuroradiologists.

Over the last decades, there has been a gradual shift from neurosurgical to non-invasive endovascular treatments of paediatric cerebral aneurysms (Fig. 90.6C).

Aneurysms undergoing endovascular treatment appear to have a higher retreatment rate which may be either endovascular or surgical. True recurrence is uncommon, but there may be a lower tolerance to small neck residuals.

Complex neurosurgical bypass procedures for fusiform lesions have been reported with good medium- and longer-term patency and clinical outcomes. This is particularly encouraging considering there must be tolerance to patient growth.

There is a slightly higher rate of aneurysm growth over time (up to 10%) in the paediatric population. This is due in part to a higher association with vasculopathies. The presence of multiple involved vessels limits the therapeutic options of parent artery closure whether endovascular or surgical as *de novo* aneurysm formation is a risk due to enhanced haemodynamic stress on already dysplastic vessels.

New flow-diversion devices have been utilized in the paediatric population for large and fusiform aneurysms. Such devices obviate the need for parent artery occlusion. Longer-term follow-up will determine durability. There are several sobering case series on paediatric aneurysm patients demonstrating late complications but also a higher than peer all-cause mortality into adult life. Late aneurysm rupture seems to be predominately related to the degree of initial aneurysm closure whether surgical or endovascular (Koroknay-Pal et al., 2012). Therefore, lifelong surveillance has been advocated by some authors. In one study, of 59 patients with a median time of follow-up of 34 years, 24 patients (41%) had 25 *de novo* and 11 recurrent aneurysms with 25% being symptomatic (Koroknay-Pal et al., 2013). New SAH occurred in seven patients. The annual rate of *de novo* aneurysm formation was 1.9%.

Smoking is a significant risk factor both for new aneurysm formation and subarachnoid haemorrhage. Patients with multiple and fusiform aneurysms at initial presentation are particularly prone to developing new lesions (Hetts et al., 2011).

Despite the requirement for more complex treatment strategies, the overall risks are not increased in the paediatric population. However, patients requiring combined or sequential surgical and endovascular treatment do have additive risks.

Arteriovenous malformations

Introduction

Despite the general acceptance that AVMs are developmental lesions and, unlike aneurysms are probably present soon after birth, they are very rare. However, haemorrhagic presentation is more common than in adults (Hetts et al., 2012), occurring in 86/135 (63.7%) of cases in one study (Ellis et al., 2015). Multimodality assessment and treatment are prerequisites to ensuring a good clinical outcome in these difficult conditions.

AVMs

Although the general architecture of AVMs does not differ substantially from the adult population in terms of nidus size, dural supply, or the number of draining veins, some differences are seen. These may relate to chronicity of high flow in the adult population as venous occlusion and stenosis, venous ectasia, and arterial flow aneurysms are all more common in adults. Deep venous drainage is seen more commonly in children. Additionally, paediatric AVMs are more commonly deep with lobar lesions being more common in adults. As with adults, paediatric patients with deep-seated AVMs, those with deep venous drainage and infratentorial lesions had a strong association with haemorrhagic presentation.

Clinical presentation, as stated is mostly haemorrhagic (up to 80%) (Fig. 90.7A), with 8.3% presenting with epilepsy and migrainous headaches (6.3%) (Dinca et al., 2012). Due to the young age at diagnosis, the calculated lifetime rupture risk is high and generally favours a more aggressive treatment approach.

Centres managing such patients should have at their disposal; experts in paediatric vascular neurosurgery; interventional neuroradiologists and access to modern stereotactic radiosurgery.

Neurosurgical resection, with or without targeted preoperative adjunct embolization, can achieve obliteration rates up to 90% with morbidity of 17% (mostly visual field defects) (Gross et al., 2015). Predictably, patients harbouring AVMs with lower Spetzler-Martin scores fare better. mRS at presentation also strongly influences the ultimate clinical outcome.

Stereotactic radiosurgery is an attractive treatment option for paediatric patients, even those with ruptured AVMs. Obliteration rates of 71.3% to 88% have been reported in selected series, with an annual bleeding rate between 1% and 2.2% per annum (Dinca et al., 2012; Hanakita et al., 2015). As with adult patients, smaller lesions have higher obliteration rates.

Endovascular therapy is perhaps much less tested and obliteration rates with endovascular treatment alone are unacceptably low at 20%, even though complication rates, as with aneurysms, are not high (Zheng et al., 2014).

Multimodality treatment probably offers the greatest benefit for patients (Fig. 90.7B). Combining complementary techniques to enhance obliteration rates can be achieved within large neuroscience centres with acceptable morbidity. In large lesions, the treatment may be ongoing for several years and almost always will require combination therapy. Haemorrhage risk persists until complete obliteration has been achieved. Clinical outcomes can be very good for small lesions, but there is a high risk of long-term dependency in survivors after treatment of very large lesions.

Cavernous malformations (CM)

CMs represent the most common central nervous system (CNS) vascular lesion in children, although their incidence is four times lower than that of the adult population (Acciarri et al., 2009).

A bimodal age distribution was found with a peak incidence under 4 years and another above 12 years. Patients under 6 years of age were found to have significantly more giant cavernomas (Bilginer et al., 2014).

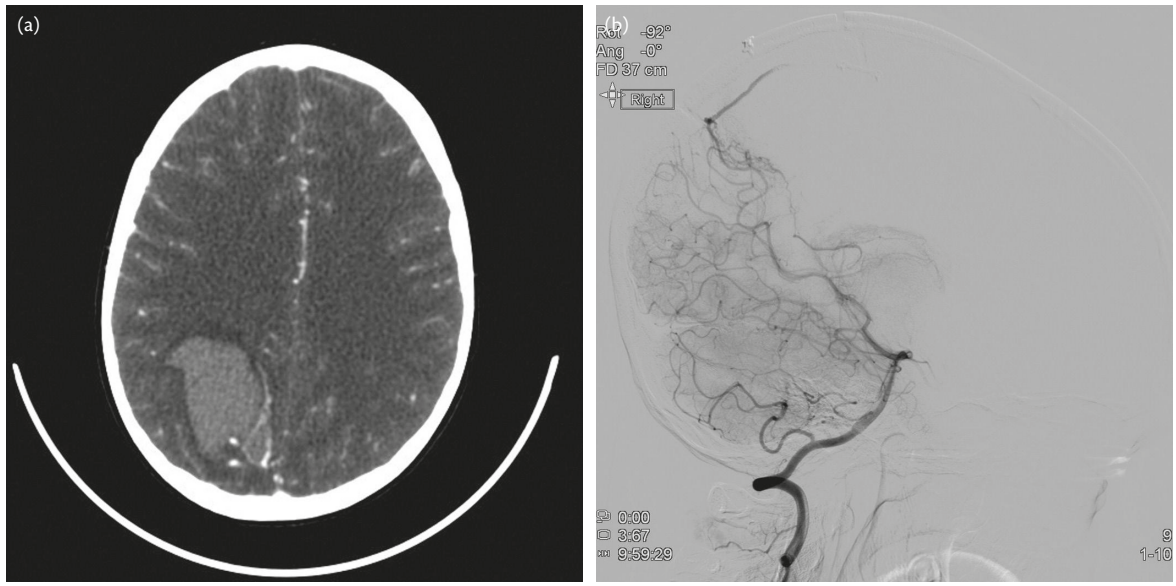

Fig. 90.7 (A) Acute cerebral haemorrhage in the right parietal lobe. CT angiography source image shows slight hypervascularity posteriorly but no definable nidus; and (B) A very small AVM is seen in the posterior right parietal lobe on catheter angiography. This was successfully managed by a combination of surgical resection and stereotactic radiosurgery.

The natural history of paediatric CMs throughout the neuraxis seems to be more aggressive than in adult patients, lesions have higher rates of growth and haemorrhage, larger dimensions, and often atypical radiological appearances at diagnosis. Beside the familial form of the disease, which is more often associated with multiple lesions and an earlier age of clinical presentation, the major risk factor for developing CMs in children seems to be cranial radiotherapy (Acciarri et al., 2009). This risk appears cumulative, the incidence of postirradiation cavernoma is 2.24%, 3.86%, 4.95%, and 6.74% within 5, 10, 15, and 20 years of irradiation. The lesions can appear from months to 20–30 years post-treatment (Strenger et al., 2008). Younger age at the time of treatment is associated with a higher cumulative risk and a shorter latency interval of formation. Conservative management is the norm for most lesions that are asymptomatic.

There is no consensus currently regarding the benefit or the interval of surveillance imaging in this group of patients.

Intracerebral haemorrhage in children

Structural lesions account for up to 50% of ICH in children. AVM's remain the commonest cause accounting for 30%, cavernomas (15%) and aneurysms (13%) are the other common structural lesions found. Other causes include Sickle cell disease, MMD, and rarely intratumoural haemorrhage. Between 10% and 30% of ICH is secondary to haematological disorders like haemophilia, thrombocytopenia, and coagulopathy secondary to vitamin K deficiency. In 25% of ICH the aetiology cannot be identified.

Presentation

Up to 45% of children may present with features of raised intracranial pressure that warrants acute management. The presentation includes severe headache, vomiting, deteriorating GCS, and seizures. Focal neurological deficits are seen in up to 50% of patients (Beslow et al., 2010).

Investigations

A CT scan is useful in identifying a bleed early. Computed tomography angiography (CTA) or MRA may be helpful in identifying an underlying structural lesion. A DSA may be necessary to identify small AVMs that may not be seen on non-invasive imaging. A DSA may need to be repeated if an underlying lesion is not identified once the haematoma has resolved.

Management

Depending upon the GCS at presentation children may need acute intervention for raised intracranial pressure (i.e. mannitol, ventricular drainage, and acute evacuation of the haematoma in up to 50% of patients). Imaging studies are helpful in identifying underlying causes and in planning the operative approach to the haematoma. The main aim of surgery is to evacuate the haematoma with or without treatment of the underlying lesion if technically feasible. Removing the underlying lesion may become necessary during haematoma removal because of uncontrolled intraoperative bleeding following evacuation of the haematoma.

Prognosis

At 3.5 months following presentation, 71% of survivors had neurological deficits and 55% had clinically significant disability (Beslow et al., 2010). The recurrence rate of ICH is 10% after 5 years.

Conclusion

Neurovascular disorders in children pose some unique challenges. They require close collaboration between multiple specialities and often combined treatment. These conditions require long-term

follow-up as these patients have many years to live with the threat of further symptoms, and disability related to both haemorrhage and treatment.

Paediatric epilepsy

Sophia Varadkar and Martin Tisdall

Introduction

Epilepsy is a disease of the brain characterized by a susceptibility to recurrent spontaneous seizures (Fisher et al., 2014). Epilepsy is common, while accurate estimates of incidence and prevalence are difficult, epilepsy occurs in 0.5–1% of the population, starts in childhood in 60% and is drug-resistant in 20–25%.

Diagnosis in children

All children, young people, and indeed adults with a recent onset suspected seizure should be seen promptly by a physician with expertise in epilepsy, to avoid misdiagnosis as well as to ensure precise and early diagnosis and to recognize serious non-neurological diagnoses, especially cardiological ones (Nunes et al., 2012).

Diagnosis is made on the clinical history. An account of the event from both the child or young person and any eyewitnesses is needed and videos can be very helpful. Physical examination should look for evidence of a focal deficit, skin features of neurocutaneous syndromes and give consideration to other systems. Note should be made of developmental and educational progress.

Electroencephalography (EEG) may lend support to the diagnosis of epilepsy but it does not confirm or refute the diagnosis. EEG helps determine seizure type and the epilepsy syndrome. It should include photic stimulation and hyperventilation. Long-term video or ambulatory EEG may be useful where there is diagnostic uncertainty. Neuroimaging identifies structural abnormalities causing epilepsy and magnetic resonance imaging (MRI) is the standard. It is not routinely required after a first suspected seizure in childhood but should be undertaken in all children presenting before the age of two years and in all with a suggestion of a focal onset on history, examination, or EEG as well as in all children who do not respond to first line medication.

In all cases, advice should be given on what to do if a second seizure occurs, safety issues must be discussed, and in some cases consideration given to emergency medicine (rescue) regimes.

Epilepsy syndromes in childhood

The electro-clinical syndromes of childhood epilepsy are comprised of clinical features, signs, and symptoms that together make a distinctive, recognizable clinical disorder. Important elements include age of onset, seizure types, specific EEG characteristics and structural-metabolic causes where present (Berg et al., 2010).

In broad terms, while neonatal seizures are often reactive/symptomatic, severe early infantile onset epileptic encephalopathies (EIEE) may present any time from birth through to early childhood. EIEE is characterized by a severe seizure disorder, often with infantile spasms, a very abnormal EEG, and developmental plateau, delay, or regression in the first year of life. A structural brain abnormality should be sought although the MRI may be lesion negative. West, Ohtahara, early myoclonic epileptic encephalopathy, epilepsy of infancy with migrating focal seizures and Dravet syndrome (severe myoclonic epilepsy of infancy) are well known. Genetic evaluation of this population is revealing an expanding list of copy number variants on array comparative genomic hybridization. Genes in association with EIEE, include the monogenic *SCN1A, STXBP1, ARX, CDKL5*, and in females *PCDH19*. Potentially treatable vitamin responsive epilepsies may also present at this age including vitamin B_6 responsive epilepsies, GLUT1 deficiency syndrome, and biotinidase deficiency.

Middle childhood (4–10 years) features some more benign conditions with good developmental and educational outcomes and greater likelihood of spontaneous remission. Well-known and most common are childhood absence epilepsy and benign epilepsy with centrotemporal spikes (BECTS); less known and thus less recognized is Panayiotopoulos syndrome. However, more serious epilepsies are also seen. Lennox–Gastaut syndrome is characterized by generalized tonic-clonic seizures, absences, drops, and tonic seizures with particular EEG patterns. Epilepsy with myoclonic absences (Doose syndrome) has variable prognosis. Epileptic encephalopathy with continuous spike and wave during sleep and Landau-Kleffner (LKS) emerge.

In later childhood (10 years onward through adolescence), the common genetic generalized (previously termed idiopathic) epilepsy syndromes appear—genetic generalized epilepsy, juvenile myoclonic epilepsy, and juvenile absence epilepsy. These are lifelong syndromes. Autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE) may have manifested earlier in childhood but only now be recognized.

At any age, specific aetiologies are recognized to cause epilepsy including neurocutaneous syndromes like tuberous sclerosis, Sturge-Weber syndrome, and Neurofibromatosis as well as

other structural lesions for example tumours or polymicrogyria. Acquired lesions such as mesial temporal sclerosis, stroke, perinatal insults, infection, and trauma, which is less commonly a cause in children than in adults, can all cause epilepsy, Distinctive constellations including Rasmussen syndrome, hypothalamic hamartomata, hemiconvulsion-hemiplegia-epilepsy, and chromosomal disorders including trisomy 21 and ring 20 may also be seen.

Medical treatment

In the United Kingdom, protocols for the treatment of prolonged seizures in children and of status epilepticus are well described (Advanced Life Support Group, 2011).

With regard to daily treatment, antiepileptic drugs (AEDs) are the mainstay. Similar to adults, carbamazepine, valproate, lamotrigine, and levetiracetam are most often used. AEDs are usually introduced with slow titration aiming for the lowest effective dose. Drug side effects may differ from those in adults. AEDs are selected by seizure type and epilepsy syndrome, and here may be different to adult practice.

The management of the comorbidities of epilepsy are of great importance in children. Motor disorders, cognitive, and learning difficulties, behavioural problems, autism, attention deficit hyperactivity disorder, or psychiatric diagnoses should be actively looked for and treated.

Drug resistance is defined as a 'failure of adequate trials of two tolerated, appropriately chosen, and used antiepileptic drug schedules (whether as monotherapies or in combination) to achieve sustained seizure freedom'(Kwan et al., 2010). This is important because the chances of seizure freedom with a further medication after two drugs have failed is less than 12%. Thus, failure of a second AED should now prompt timely referral for consideration of other treatments, including epilepsy surgery, the ketogenic diet, and in children who are not candidates for resective epilepsy surgery, neurostimulation with vagus nerve stimulation (VNS) therapy.

Presurgical evaluation of a child for epilepsy surgery

Epilepsy surgery removes, disconnects, or ablates brain parenchyma assumed to generate ictal epileptic (seizure) activity with the primary aim of seizure freedom or significant improvement of seizures, without detriment to function. Careful presurgical evaluation (PSE) in a centre with expertise in epilepsy surgery for children should determine the area of seizure onset, and also minimize the risk that surgery might lead to significant impairments (**Fig. 91.1**). The 2006 International League Against Epilepsy (ILAE) subcommission for paediatric epilepsy surgery recommendations for referral and evaluation of children remain relevant, and are being updated (Cross et al., 2006). Technological advances are enhancing PSE and mean that MRI lesion-negative children are also potential candidates for surgery.

Special considerations in children

There is no minimum age for presurgical evaluation, indeed PSE should begin as early as possible to shorten the duration of disease and minimize the impact of a long-term seizure burden. Identification of potentially surgically remediable epilepsy in children may be complex. Semiology is often less helpful, especially in the younger age groups and is less lateralizing than in adults. Additionally, children presenting with apparently generalized features, such as epileptic spasms, may have a focal seizure onset zone, but with rapid spread of ictal activity. Imaging interpretation in children is complex and requires specialized paediatric neuroradiologists, well versed in the changing appearances of the paediatric brain over time. In young children under the age of 2 years, prior to the completion of myelination, lesional abnormalities may not be appreciated and repeat imaging over several years may be needed to identify surgical cases. The psychosocial effects of paediatric epilepsy are taking place against the background of changing cognitive development and the timing of surgery will therefore be influenced by developmental trajectory. Cognitive outcome will be optimized by earlier surgery and its attendant potential for drug reduction (Boshuisen et al., 2015).

Components of the presurgical evaluation

The components of an initial (now termed phase 1) PSE remain essentially unchanged from the 2006 recommendations: interictal scalp EEG (including sleep), a dedicated MRI brain epilepsy protocol, long-term ictal scalp video-EEG where possible, neuropsychology assessment and where needed functional MRI (fMRI) (Ryvlin et al., 2014). We believe neuropsychiatry and neuro-ophthalmology should also be included. Extended phase 1 investigations include positron emission tomography, magnetoencephalography (MEG), EEG-fMRI, electrical source imaging, and high-resolution EEG. Ictal and interictal single-photon emission CT (SPECT) with postprocessing analysis for ictal focal brain hyperperfusion can be useful in delineating candidate tubers in tuberous sclerosis and to localize the epileptogenic zone (EZ) in lesion-negative cases.

Underlying conditions

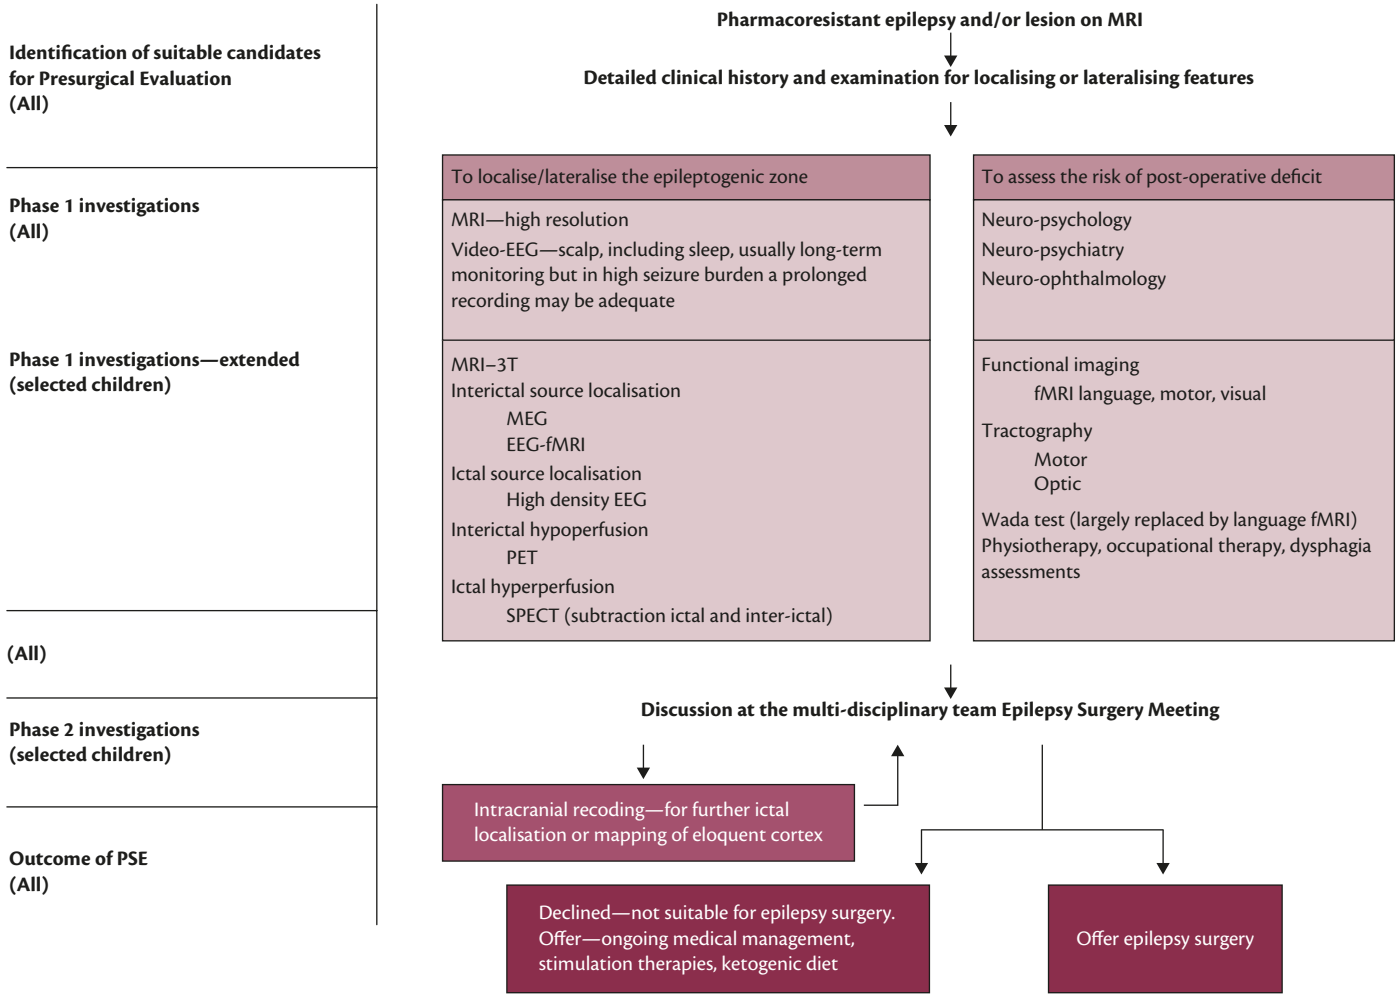
In 2004, the ILAE carried out a survey of international paediatric epilepsy centres. Hippocampal sclerosis, which forms a large proportion of cases in contemporary adult series, was relatively underrepresented in paediatric series whereas cortical dysplasia forms the largest group (Pellock et al., 2008). The incidence of various conditions is shown in **Table 91.1**) (Pellock et al., 2008).

Operation type

Lobar and focal resections provide the bulk of surgical procedures in most paediatric epilepsy surgery centres. However, the proportion of multilobar and hemispheric procedures is greater than in adult series. The 2004 ILAE survey demonstrates the range of procedures in paediatric centres (**Table 91.2**) (Pellock et al., 2008).

Surgical considerations

The principles of epilepsy surgery remain similar in both adult and paediatric procedures and comprise the maximum removal of presumed lesional tissue while minimizing damage to eloquent



Identification of suitable candidates for Presurgical Evaluation (All)
Pharmacoresistant epilepsy and/or lesion on MRI
Detailed clinical history and examination for localising or lateralising features
Phase 1 investigations (All)
To localise/lateralise the epileptogenic zone
MRI—high resolution
Video-EEG—scalp, including sleep, usually long-term monitoring but in high seizure burden a prolonged recording may be adequate
To assess the risk of post-operative deficit
Neuro-psychology
Neuro-psychiatry
Neuro-ophthalmology
Phase 1 investigations—extended (selected children)
MRI–3T
Interictal source localisation
MEG
EEG-fMRI
Ictal source localisation
High density EEG
Interictal hypoperfusion
PET
Ictal hyperperfusion
SPECT (subtraction ictal and inter-ictal)
Functional imaging
fMRI language, motor, visual
Tractography
Motor
Optic
Wada test (largely replaced by language fMRI)
Physiotherapy, occupational therapy, dysphagia assessments
(All)
Discussion at the multi-disciplinary team Epilepsy Surgery Meeting
Phase 2 investigations (selected children)
Intracranial recoding—for further ictal localisation or mapping of eloquent cortex
Outcome of PSE (All)
Declined—not suitable for epilepsy surgery. Offer—ongoing medical management, stimulation therapies, ketogenic diet
Offer epilepsy surgery

Fig. 91.1 Presurgical evaluation pathway.

tissue. Resection is often planned to include tissue up to the next pial boundary surrounding a lesion. Dual pathology appears more prevalent in paediatric cases and especially so for temporal resections. There has therefore been less movement towards more selective resective strategies for hippocampal sclerosis than in adult practice. Seizure freedom remains the most important determinant of postoperative cognitive function (Skirrow et al., 2015) and so more extensive temporal lobe resection to include neocortical as well as mesial structures is generally thought to be beneficial as the larger volume of resection may improve seizure outcome despite removing potentially functional tissue.

In children, the brain weighs proportionally more compared to body weight than in adults. Additionally, young patients often

Table 91.1 Incidence of underlying conditions in paediatric epilepsy surgery

Aetiology	Percentage of cases
Cortical dysplasia	42%
Tumour	19%
Infection/stroke/trauma	10%
Hippocampal sclerosis	6%
Tuberous sclerosis	5%
Hypothalamic hamartoma	4%
Sturge-Weber syndrome	3%
Rasmussen syndrome	3%
Vascular lesion	1%
Other	7%

Table 91.2 Procedure type in paediatric epilepsy surgery

Surgical procedure	Percentage of cases
Lobar/focal lesionectomy	48%
Hemispherotomy	16%
Multilobar resection	13%
Vagus nerve stimulator	16%
Corpus callosotomy	3%
Other	4%

Source data from Pellock, J. et al., 2007. *Pediatric Epilepsy*, New York: Demos Medical.

require large cortical resections which can be associated with significant blood loss relative to total blood volume. Great attention must be paid by both surgeon and anaesthetist to ensure adequate haemostasis and resuscitation and this highlights the need for a dedicated surgical and anaesthetic team able to predict and pre-empt operative issues.

Detailed descriptions of the principles of lesionectomy and amygdalohippocampectomy are covered in Chapter 83 and will not therefore be covered further here.

Hemispherectomy/Hemispherotomy

Hemispherectomy or hemispherotomy is a surgical procedure which aims to either resect or disconnect the entire cortex of one cerebral hemisphere. It was first introduced in 1928, by both Dandy and L'Hermitte, as a treatment for hemispheric glioma and although it did not improve prognosis in this patient group it has subsequently become an important technique in epilepsy surgery. Multiple technical variations have been proposed and these will be discussed next. For convenience, we will use the term hemispherotomy to encompass all procedures aimed at hemispheric resection or disconnection.

Indications for hemispherotomy include drug-resistant epilepsy which is hemispheric, or from multilobar pathology where less extensive resection is unsuitable, and seizures are deemed to be arising from the involved hemisphere. The contralateral hemisphere must be deemed healthy and there should be an existing hemiparesis. Over time the indications have widened and those mentioned can be considered relative. All potential cases should be discussed at an experienced multidisciplinary epilepsy surgery meeting.

Surgical decision-making will also take account of seizure burden and developmental trajectory, and 'palliative' hemispherotomy may be considered in some cases. Recent work has suggested that contralateral hemisphere MRI and EEG abnormalities may not affect prognosis in selected cases (Wyllie et al., 2007; Hallbook et al., 2010).

Pathologies in which hemispherotomy is indicated include hemimegalencephaly, migration disorders, cortical dysplasia, cerebral infarction, porencephaly, Sturge-Weber, and Rasmussen syndromes.

Functional consequences of hemispherotomy

All variants of this procedure involve interruption of the ipsilateral internal capsule and optic radiation. The inevitable consequence is contralateral hemiparesis and homonymous hemianopia. The effect of surgery depends on the preoperative functional status, age of the child, and preoperative cognitive ability. At one end of the scale a child with a hemispheric perinatal infarct with pre-existing dense hemiparesis and hemianopia will have minimal or no functional change after hemispherotomy. At the other extreme, a child with dominant hemisphere Rasmussen syndrome may have significant changes in language function, motor function, and vision. Decision-making in these latter cases is obviously complex and requires careful discussion with both patients and carers.

Technical evolution

Anatomic hemispherectomy for epilepsy was first described in 1938. In the 1960s it became apparent that the procedure was associated with a high risk of postoperative neurological deterioration secondary to superficial siderosis (secondary to recurrent haemorrhage into the surgical cavity) and hydrocephalus (Beier and Rutka, 2013). Subsequent techniques have seen a move towards cortical disconnection rather than resection. Rasmussen used the term functional hemispherectomy to describe a technique in which the central and temporal regions are resected with the frontal and occipital regions being disconnected. Further technical developments have led to a variety of hemispherotomy procedures involving little or minimal tissue resection with the aim of reducing operative time and blood loss (Villemure and Mascott, 1995; Dorfer et al., 2013). The choice of technique will depend on the surgical experience of the team and the underlying brain anatomy.

Technique

Currently two main approaches predominate, either lateral hemispherotomy centred on the insula region with the bulk of the procedure being performed through the ventricular system or alternatively a vertical parasagittal technique may be used.

Regardless of the technique used the following must be achieved; disconnection of the ipsilateral internal capsule, disconnection of mesial temporal structures, complete corpus callosotomy, and disconnection of horizontal frontal fibres.

Complications include haemorrhage, infection, postoperative non-infectious fever, aseptic meningitis, contralateral stroke, cerebral infarction, or oedema, hydrocephalus requiring a ventricular shunt in 10–15% and death in 1–3%.

Hemispherotomy outcome depends on the underlying pathology with overall seizure freedom of 70–80%. Outcome is better for acquired or progressive pathologies as opposed to those of developmental aetiology. The outcome is not affected by the surgical technique used. See **Box 91.1**.

Invasive monitoring

Invasive monitoring is a technique in which electrodes are placed either into, or over the surface of the brain, in order to record ictal and interictal activity with higher spatial resolution than is possible with a scalp EEG. Electrodes are usually left in place for approximately 7 days in order to collect sufficient data. These techniques also allow for electrical stimulation of the brain through the electrodes in order to delineate eloquent cortex or to identify epileptogenic networks. This may be especially useful in young children in whom awake craniotomy may not be an option.

Two techniques predominate: subdural grids can be placed via a craniotomy or multiple stereotactically placed depth electrodes can be placed percutaneously using neuronavigation (stereoEEG). The two methodologies have differing advantages, but in general terms subdural grids offer higher resolution mapping whereas stereoEEG gives better coverage of deep and mesial cortical areas. See **Box 91.2**.

Surgical procedures for the palliation of paediatric epilepsy

A proportion of patients with severe and medically refractory epilepsy will not be candidates for resective surgery. In this set of patients, consideration may be given to palliative surgical procedures

Box 91.1 Case study 1

A 5-month-old was referred with onset of infantile spasms at age 2 weeks. She was drug responsive at initial review and making good developmental progress other than fisting of the left hand. MRI showed a widespread malformation of cortical development affecting the right cerebral hemisphere (Fig. 91.2) and EEG revealed a chaotic pattern over the right hemisphere. Seizures recrudesced at the age of 12 months and she underwent a right hemispherotomy without complications. At 1-year follow-up she was seizure-free and making good developmental gains, with only a mild increase in tone on the left-hand side.

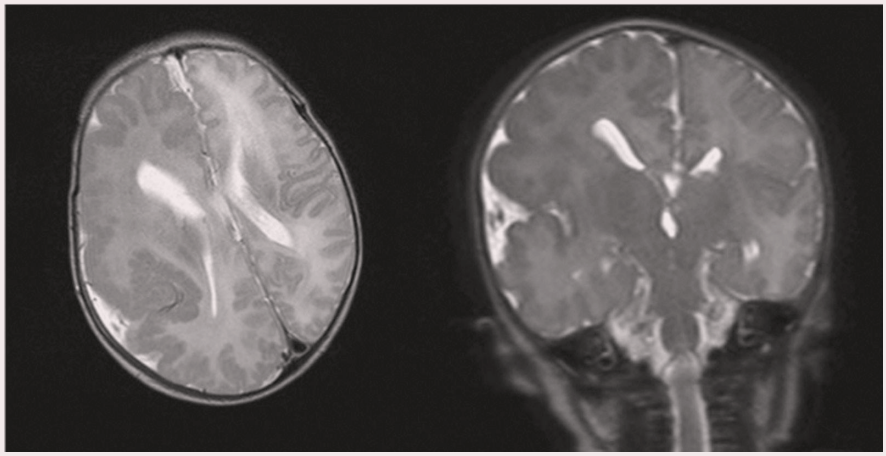

Fig. 91.2 Axial and coronal T2 MRI of a 5-month-old child showing extensive cortical malformation and polymicrogyria affecting right hemisphere.

Box 91.2 Case study 2

A 16-year-old boy had seizures with frontal lobe semiology of onset at 8 years. He had failed treatment with five AEDs. Other than some specific difficulties with memory, he had normal neurocognition. An MRI was initially felt to be lesion negative. Extended imaging identified a subtle right middle frontal gyrus lesion and after stereoEEG implantation (Fig. 91.3) he underwent successful lesionectomy. Histology was of a focal cortical dysplasia. He is seizure free and off all AEDs at 1-year follow-up.

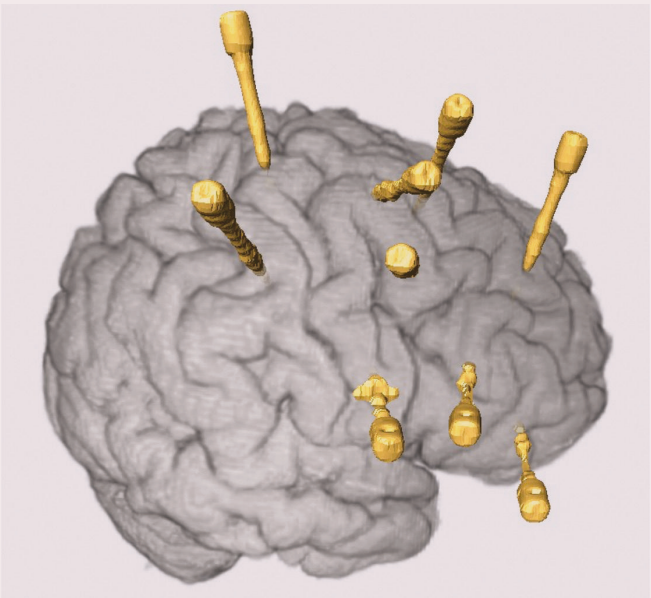

Fig. 91.3 Postoperative stereoEEG imaging demonstrating implanted electrode locations coregistered with segmented cortex.

aiming to reduce the frequency or severity of seizures with a view to improving quality of life.

Indications for palliative epilepsy surgery include generalized or multifocal seizures where there is an inability to localize the seizure source or where seizures arise from eloquent cortex where the risk to eloquent tissue is deemed unacceptably high.

Palliative epilepsy surgery techniques include corpus callosotomy, VNS, and multiple subpial transections

Corpus callosotomy

Sectioning of the corpus callosum is most effective in patients suffering with atonic (drop) seizures with lesser efficacy against tonic seizures. Complete callosotomy leads to approximately a 70% reduction in drop attacks in 70% of patients. Complete corpus callosotomy has a higher chance of seizure reduction as opposed to partial callosotomy (Kasasbeh et al., 2014). The incidence of postoperative disconnection syndrome in paediatric series is extremely low and this relates, in part, to the fact that most children in which this procedure is indicated, have significant developmental delay, and pre-existing communication impairment. In contrast to adult practice, we perform complete callosotomy in the vast majority of paediatric candidates with partial, anterior two-thirds, callosotomy reserved for children with little or no cognitive impairment.

A craniotomy crossing the midline is used and an interhemispheric approach to the corpus callosum is made. Arachnoid scarring is often encountered and great care must be taken to divide adhesions. The corpus callosum is then divided from rostrum to splenium.

Vagus nerve stimulation (VNS)

The hypothesis that vagus nerve stimulation might attenuate epileptic seizures was first proposed in 1985.

This was subsequently supported by animal studies and human clinical trials. VNS has similar efficacy to corpus callosotomy but without the attendant risks of intracranial surgery.

VNS involves implanting a stimulating electrode around the left vagus nerve (chosen to reduce the risk of cardiac effects) and connecting it to a subcutaneous stimulator placed most commonly in the pectoral region. The stimulator is set to a background discharge setting and can be triggered to an on-demand setting by swiping a magnet across the device. The latest version of the device senses heart rate and has an algorithm designed to detect seizure related tachycardia, which then automatically triggers the on-demand setting, with the aim of terminating the seizure (Schneider et al., 2015).

Multiple subpial transections (MST)

MST is a technique in which multiple transection are made at 5 mm intervals perpendicular to the gyral long axis in the presumed epileptogenic zone. The aim is to disrupt lateral cortico-cortical connections leaving cortical areas without the required critical mass required to sustain development of seizures, yet preserving the vertical cortico-subcortical pathways required for function.

MST has been used in conditions where epileptogenesis is presumed to arise from eloquent cortex and in particular gained popularity in the treatment of Landau-Kleffner syndrome. It has recently become less popular as it causes cortical damage and its efficacy has been questioned.

Choice of procedure

Corpus callosotomy and VNS may have synergistic effects. Corpus callosotomy appears to have greater efficacy in patients with atonic seizures, yet carries the risks of intracranial surgery. We would recommend corpus callosotomy as the initial surgical approach in those patients where atonic seizures predominate or where they are thought to have the greatest effect on quality of life.

Previously it was not possible to perform detailed MRI scans in patients with a VNS *in situ* however this has been addressed by modern MRI scanner design and VNS need not now preclude future evaluation for epilepsy surgery.

Controversies in paediatric epilepsy surgery

Timing of hemispherotomy surgery in dominant hemisphere Rasmussen's syndrome

Rasmussen's syndrome is characterized by refractory seizures, unilateral cortical atrophy, and associated neurological deficits. Hemispherotomy surgery remains the only cure and provides a 70–80% chance of seizure freedom (Bien and Schramm, 2009). Nevertheless, this surgical strategy has inevitable consequences of homonymous hemianopia, hemiplegia and, in patients with dominant hemisphere involvement, language dysfunction. These deficits may be present preoperatively, yet their severity, and speed of onset, varies. Cognitive decline is common, yet not inevitable, and may be heralded by the appearance of independent interictal epileptiform discharges over the contralateral hemisphere (Longaretti et al., 2012). Short duration between seizure onset and surgery is generally associated with better cognitive outcome and early surgery is, therefore, often thought to be beneficial (Jonas et al., 2004). The degree of language transfer after hemispherotomy relates primarily to age at the start of the disease process and in suitable patients may be assessed using language fMRI or Wada investigation. Controversy exists as to whether this language function transference to the contralateral hemisphere is driven best by early surgery, when neural plasticity may be retained, or whether it is best achieved by waiting for the disease process to progress in an attempt to allow function to become established naturally in the unaffected hemisphere (Hartman and Cross, 2014). Even when dominant language function remains in the affected hemisphere at the time of surgery, it is rare to produce complete aphasia (Boatman et al., 1999). Receptive function is generally retained although expressive language may be significantly reduced. Decisions around the timing of surgical treatment must be guided by the severity of seizures, and assessment of both the degree and evolution of neurological deficits (Varadkar et al., 2014). This is a challenging situation for families and clinicians and requires evaluation of the likely final outcomes of both surgical and conservative approaches.

Hydrocephalus and normal CSF dynamics

Alexander Gamble and Harold Rekate

Introduction

The first investigations into the nature of CSF dynamics began in the late 1800s. These works paved the way for a renaissance in the elucidations of CSF physiology that occurred between the second and sixth decades of the 1900s. Pioneering research established the basic principles upon which rests nearly all our understanding of CSF production, circulation, and absorption. CSF physiology and hydrocephalus continues to be an active area in neuroscience research to this day. The general hydrodynamic behaviours of CSF were accurately described long ago but their underlying mechanisms have been a source of controversy in the neurosciences to this day. This chapter serves to define the most effective and robust theories governing CSF dynamics and the aetiologies behind many of the hydrocephalic states. This chapter should serve as a general review, or as a starting point to the reader whose goal is to explore the larger body of knowledge pertaining to cerebrospinal hydrodynamics.

Hydrocephalus

Hydrocephalus is a condition characterized by a dynamic imbalance between the formation (production) *and absorption* of spinal fluid resulting in an increase in the size of the ventricular spaces. In the most rudimentary sense, cerebrospinal fluid (CSF) resembles a body of water behind a floodgate. Fluid accumulates behind the closed floodgate and when a sufficient level is achieved, the excess will flow over this barrier. The volume expelled would be proportionate to its height above the barrier, automatically maintaining a constant volume in the circulating pool. Hydrocephalus would be akin to inappropriately raising the level of the floodgate with a resultant increase in the volume of fluid contained behind it. Our initial solution as neurosurgeons has been to drill a conduit from the floor of the reservoir to a point downstream of the floodgate, subverting the physics that would normally control the local environment. Even with a proper valvular mechanism to regulate flow through our artificial conduit, the laws governing flow out of the system have been reversed from a passive, self-regulating overflow mechanism to an active siphon. Although overly simplistic, this metaphor illustrates the imposition of a non-homeostatic strategy on a natural system. We can surmise that much like in our natural world, unintended consequences will arise when disrupting complex natural systems, analogous to the difficulties we encounter as neurosurgeons in the management of complex hydrocephalic patients.

CSF diversion with shunting devices remain the primary treatment option for hydrocephalus but comes with alarmingly high rates of failure and complication, sometimes with disastrous consequences. Hydrocephalus was largely untreatable and fatal until the mid-twentieth century with the advent of valve-regulated CSF shunts (Nulsen, 1951). Approximately, about 0.5–0.8/1000 infants born in developed countries will be afflicted with the condition (Garne et al., 2010; Jeng et al., 2011) and the majority will depend on a shunt. At the other end of the spectrum, it is estimated that around 700 000 individuals in the United States and 2 million in Europe suffer from normal pressure hydrocephalus (NPH) (Jaraj et al., 2014). Those responding to a shunt can enjoy an additional six quality adjusted life years, which is roughly equivalent to the benefit derived from coronary artery bypass grafting or surgery for breast cancer (Stein et al., 2006).

Role of CSF in the central nervous system (CNS)

The human brain, representing only 2% of body mass requires 15% of cardiac output, 20% of oxygen consumption, and a quarter of total body glucose utilization. The incredible complexity and energy expenditure as compared to other animals is paralleled by a commensurate increase in total CSF production and absorptive capacity. CSF fulfils multiple roles in the maintenance of brain homeostasis. It provides a buoyant force, cushioning nervous tissue within its rigid case of bone. The CSF volume serves as a capacitor to dampen the rapid fluctuations of blood volumes and pressures experienced throughout the cardiac cycle. As the arachnoid

Table 92.1 Comparison of CSF composition to plasma

Concentration (mg/100 ml^{-1})		
	CSF	Plasma
Protein	16–38	6300–8500
Glucose	45–80	80–120

villi are capable of transferring particles on the order of a few microns into the systemic circulation, circulating CSF is able to clear not only metabolic wastes, but large proteins and cellular debris as well. A growing number of growth factors, hormones, vitamins, and micronutrients have been shown to be directly excreted into CSF for the purpose of distal delivery to their target cells via CSF pathways.

Neurons require tight regulation of their extracellular environment for optimal function. In brain parenchymal extracellular fluid (ECF) and CSF, the concentration of ions and macromolecules are effectively maintained within very narrow ranges. The blood–brain barrier (BBB) and blood CSF barrier (BCSFB) maintains disparate solute concentrations as compared to plasma as demonstrated in Table 92.1. The unique anatomical microcirculation of the brain tightly and selectively regulates passage of molecules and electrolytes. These barriers are on the order of ten times less permeable to the flow of water and at least a thousand times less permeable to the flow of organic and inorganic solutes than that of the fenestrated endothelium present in most other peripheral tissues. Although the transfer of solutes into brain ECF and CSF from plasma is an ultra-selective, active process, the movement of water between physiological compartments is passive but equally precise, as water will always follow solute concentration. The physical arrangement of endothelial cells and glial cell foot processes comprising the BBB is also able to withstand increased hydrostatic and osmotic forces far better than other organs. This serves to protect brain tissue from becoming oedematous secondary to increased filtration driven by blood pressure or low plasma oncotic pressure. Chronic hypertension or oedematous states caused by low serum protein content are well tolerated by the CNS whereas their effects elsewhere in the body may be rapidly deleterious.

Changes in CSF physiology in age and disease

CSF production decreases with age owing to fibrosis of choroid plexus and a decrease parenchymal volume as neurons and glia are lost to senescence. The total CSF volume roughly doubles from young adulthood to the seventh and eighth decades (Courchesne et al., 2000). Taken together, there is a progressive diminution in CSF turnover, reflecting a relative stagnation of CSF with advancing age. In childhood, replacement rates may be as high as 6×/day, 4×/day in young healthy individuals and drops to 3×/day or less in normal elderly individuals (May et al., 1990; Serot et al., 2012).

In NPH and Alzheimer's dementia (AD), CSF replacement is even more dramatically reduced (see Table 92.2). Animal models of both AD and NPH demonstrate beta amyloid peptide (Aβ) and tau protein accumulation in brain tissue and that specific clearance pathways for those substances are impaired. (Shibata et al., 2000; Silverberg et al., 2010). Transthyretin (TTR) is produced exclusively by choroid plexus epithelium (Sousa et al., 2007) is the main chaperone of thyroxin (T_4), binds to Aβ monomers preventing fibril formation and provides a means of amyloid excretion out of the CNS (Redzic et al., 2005). There is a clear inverse correlation between ventricular volume and CSF Aβ levels in patients with mild cognitive impairment and frank AD (Ott et al., 2010). It is entirely plausible that this correlation ultimately results from the primary disease processes and does not necessarily substantiate cause and effect. That being said, the disturbances in fluid physiology observed in senescence, AD, and NPH are difficult to ignore and may play a significant role in their pathophysiology.

There may be more overlap between AD and NPH pathologies than previously understood. Whether both diseases can exist simultaneously is highlighted by the fact that CSF markers or tissue biopsy may not clearly delineate one from the other or responsiveness to CSF diversion in any individual patient (Golomb et al., 2000; Ott et al 2010). After strengthening the suspected clinical diagnosis of NPH with a 24-hour ICP monitoring, Leinonen et al. (2010) collected frontal brain biopsies at the time of shunt placement in 219 patients. Of the 168 (77%) patients who benefited from the shunt, 52 (31%) displayed AD-related pathology and 13 (25%) of them had developed clinical AD by the end of the follow-up. Some 69% of patients did not display AD-related pathology at shunt placement, but six still (5%) developed confirmed AD. Disappointingly, a recent large, double blinded, randomized, placebo-controlled trial of low-flow ventriculoperitoneal shunting in 215 AD patients failed to show

Table 92.2 CSF changes in normal pressure hydrocephalus and Alzheimer's disease (Hladky and Barrand, 2014)

	Normal	NPH	AD
Formation (ml/min)	0.4	0.25	0.2
Volume (ml)	150	300	250
Turnover rate (vol/day)	4	1.2	1.2

Adapted with permission from Johanson, C.E., Duncan, J.A., Klinge, P.M., Brinker, T., Stopa, E.G. & Silverberg, G.D., Multiplicity of cerebrospinal fluid functions: New challenges in health and disease, *Cerebrospinal Fluid Research*, Volume 5, Issue 10 Copyright © 2008 Johanson et al; licensee BioMed Central Ltd.

any clinical benefit or a decrease in CSF tau or Aβ levels (Silverberg et al., 2008). An important caveat to these negative results is that although a shunt can drain CSF, it cannot increase CSF production. Thus, the rate of CSF replacement would be dependent on the loss of ventricular volume which is usually not observed in shunted AD or NPH patients.

Production of CSF in the CNS

Parenchymal production

The total volume of brain ECF is estimated at around 280 ml (Johanson et al., 2008) and its total contribution to CSF volume is probably around one-third. This is a best estimate as the true contribution is virtually impossible to define by today's methods. The cytoarchitecture of central nervous tissue has evolved devoid of lymphatic vessels that would normally drain the ECF that is not reabsorbed into the venous circulation. This should not be confused with the concept of terminal CSF absorption via nasal lymphatics interfacing with arachnoid at the skull base. Lymphatic drainage is a necessary physiologic process because not all of the fluid that leaves the vascular compartment into the extracellular space can be reabsorbed into the venous circulation. Generally speaking, about 1% of the plasma volume delivered to a capillary bed will enter the extracellular space at the proximal end. About 90% of this filtrate is reabsorbed into the circulation as we move to the most distal postcapillary venules. Thus, depending on the tissue, approximately 0.1% of the delivered plasma volume delivered to the end organ ultimately becomes lymph. The ECF of brain parenchyma functions similarly to lymph in other tissues. It serves as a route for removal of cellular wastes, especially those of higher molecular weights. In addition to the water generated by metabolism itself, this extracellular fluid ultimately mixes with and flows into the ventricular and subarachnoid CSF spaces. Ependymal cells are linked together by gap junctions as opposed to the tight junctions observed at the BBB, allowing for a relatively free equilibration of solute and water between extracellular and ventricular spaces. CSF derived from the choroid plexus differs from the parenchymal ECF in that it is relatively pure of metabolic and cellular wastes. These properties create a concentration gradient driving ECF solutes into ventricular CSF so that the absorptive processes that will be discussed later in this chapter may ultimately excrete them into the venous circulation.

The choroid plexus

The choroid plexus epithelium (CPe) is responsible for production of at least two-thirds of the total CSF production in humans. CPe is traditionally thought of as not possessing a blood–brain barrier like the brain parenchyma and brightly enhances on contrast-enhanced neuroimaging. This does not imply a lack of selectivity, as a very effective blood CSF barrier (BCSFB) exists in the CPe that is ultrastructurally distinct from the BBB and uniquely specialized. Tight junctions between the cuboidal epithelial cells limit the flux of ions and water. The choroid plexus is highly vascular, receiving supply from the anterior and posterior choroidal arteries at a rate of 3–4 ml per minute, ten times greater than that of grey matter. Unlike other endothelial cells in the CNS, fenestrations are large allowing access to a high volume of plasma filtrate at the basolateral membrane. The basolateral membrane contains many infoldings and the apical, ventricular facing membrane is equipped with extensive microvilli demonstrated in **Figure 92.1**. These attributes, coupled with a branching, frond-like macroscopic architecture is what allows the approximate 2 total grams of CP present in the ventricles to secrete such a large daily volume.

Mechanisms of CSF formation in the choroid plexus

Although the fluid available basolaterally to CPe cells is a plasma ultrafiltrate, the fluid produced at the apical brush border is not. Electrolyte concentrations are highly and specifically regulated. The Na^+-K^+-ATPase in CPe is localized to the apical membrane, which is the opposite configuration to that in most other tissues. This sets up the major energy-dependent electrochemical gradient driving subsequent cotransport as well as being the primary source of CSF sodium. Oubain, a potent cardiac glycoside inactivates the pump and significantly decreases CSF production. The low intracellular sodium gradients created by Na^+–K^+–ATPase drive basolateral H^+ and Na^+ exchangers (NHE1), sodium dependent Cl^- –HCO_3 exchangers and Na^+–HCO_3 cotransporters. The Na^+–HCO_3 cotransporter is inhibited by the diuretic amiloride, which also reduces CSF production. Translocation of sodium across both membranes into the ventricular lumen drives chloride transmission as well, maintaining electrochemical neutrality. In addition to high intracellular K^+, this drives apical Na^+–K^+–$2Cl^-$ (NKCC1) cotransporters that are inhibited by loop diuretics, which also decrease CSF production.

The discovery of selective water channels, or aquaporins and the potential roles they play in the regulation of brain water physiology has greatly enhanced our understanding. Aquaporin-1 (AQP-1) is expressed at high levels almost exclusively along the apical membrane of the CPe in the CNS (Longatti et al., 2004; Praetorius and Nielsen, 2006). The CPe is also devoid of AQP-4, which is expressed almost exclusively on astrocytic foot processes at the BBB. AQP-1 knock-out mice produce 20–25% less CSF and have ~50% lower mean ICP values than wild-type mice (Oshio et al., 2003; Oshio et al., 2005) Downregulation of AQP-1 has also been demonstrated in animal models of hydrocephalus (Paul et al., 2011). The discovery of AQP-1 in this location reconciles the reality of CPe's ability to translocate water through a BCSFB in volumes that violated our previous understanding of a cell membrane's capabilities. Tight regulation of net solute transport results in precise translocation of water, much like that of the BBB but amplified many fold, due to the presence of AQP-1. These insights make AQP-1 an interestingly viable molecular target for future pharmacological treatment of hydrocephalus.

The enzyme carbonic anhydrase (CA) is expressed in several isoforms, some apically and basolaterally membrane bound, and others in soluble forms functioning in the cytosol. Though not directly involved in transport, the enzyme creates bicarbonate and hydrogen from water and carbon dioxide. The CA inhibitor acetazolamide is a very effective inhibitor of CSF production by reducing the H^+ and HCO_3 available for cotransport as well as altering overall CPe physiology by increasing cellular pH. Chronic acetazolamide administration also attenuates microvilli at the apical border, significantly reducing surface area needed for excretion (Azzam et al., 1978).

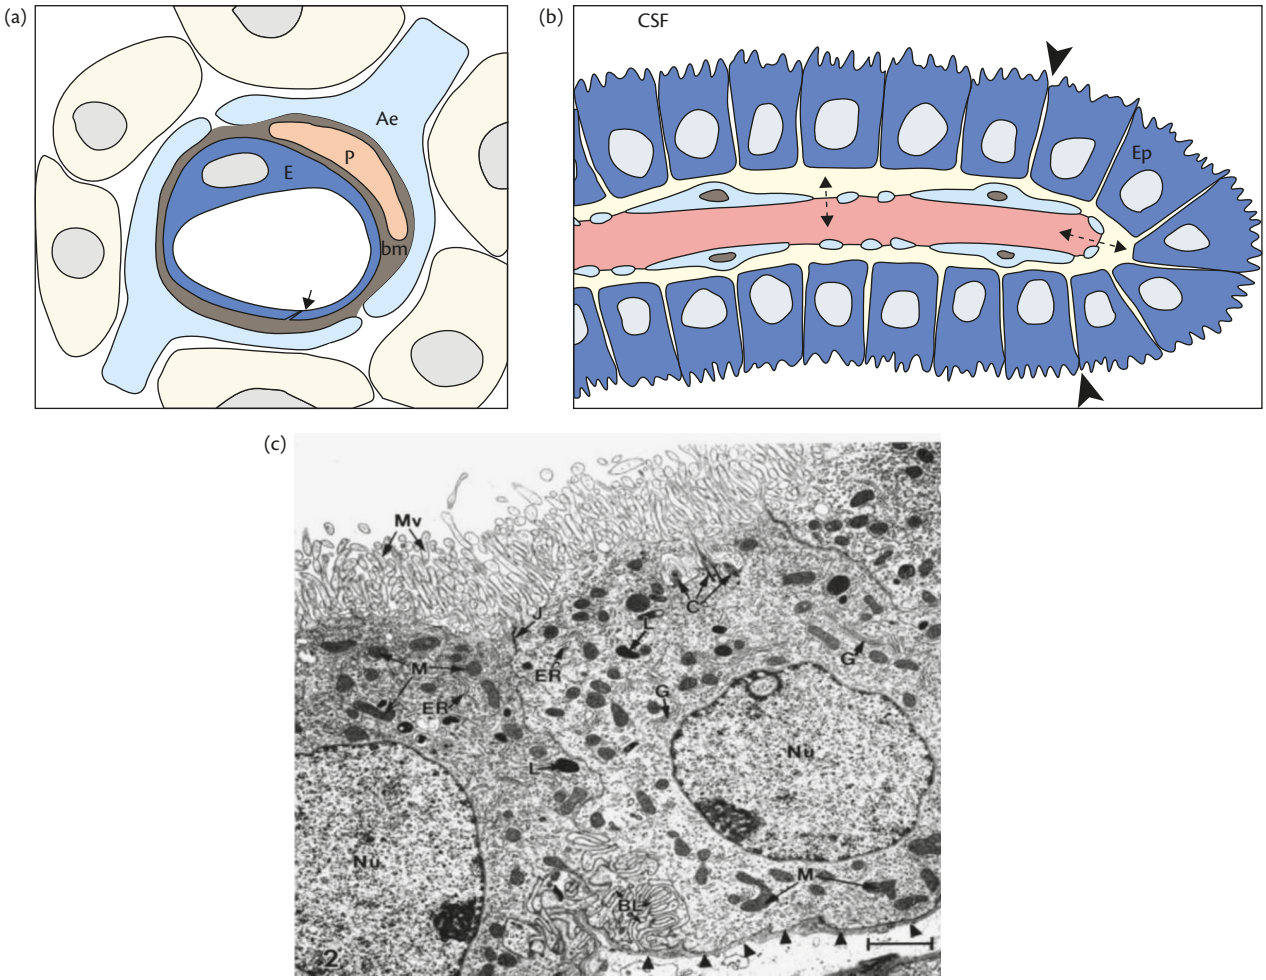

Fig. 92.1 Blood CSF and blood–brain barriers.

Schematics of the brain barriers. Barrier interfaces in the brain are indicated in blue. The primary site of the blood–brain barrier (A) is the endothelial cells of the cerebral blood vessels (E), supported by pericytes (P) and astrocytic endfeet (Ae). In the choroid plexus (B) the epithelial cells (Ep) are the barrier interface of the blood CSF barrier, as the endothelial cells in the stroma are fenestrated (Stolp et al., 2012).

(C) Ultrastructure of choroid epithelium. CP from a lateral ventricle of an untreated adult Sprague-Dawley rat was fixed for electron microscopy with OsO4. There is a profusion of apical membrane (CSF-facing) microvilli (Mv) and many intracellular mitochondria (M). J refers to the tight junction welding two cells at their apical poles. C = centriole. G and ER, Golgi apparatus and endoplasmic reticulum. Nucleus (Nu) is oval and has a nucleolus. Arrowheads point to basal lamina at the plasma face of the epithelial cell; the basal lamina separates the choroid cell above from the interstitial fluid below. Basal labyrinth (BL) is the intertwining of basolateral membranes of adjacent cells. Choroidal morphology resembles proximal tubule, consistent with both cell types rapidly turning over fluid. Scale bar = 2 μm.

Trophic and protective function of choroid plexus

Many proteins implicated in neuronal development, maintenance and repair are produced in CPe and secreted into CSF such as: insulin-like growth factor-2 (IGF-2), members of the transforming growth factor-β (TGF-β) superfamily, bone morphogenic proteins (BMPs), fibroblast growth factors (FGFs), and retinoic acid (RA). These species have many implications in normal CNS development and injury response. CSF glucose levels approximately two-thirds that of plasma are regulated by CPe GLUT1 transporters present on the basolateral membrane. Similarly, stable concentrations of amino acids in the CSF are maintained by their respective transport mechanisms. CPe also contains specific nucleoside transporters removing purine and pyrimidine metabolites such as adenosine, which can appreciably alter neuronal function. Very high levels of the detoxifying and conjugating enzymes such as epoxide hydrolase, glutathione peroxidase, and UDP-glucuronosyltransferase among others have been measured in choroid plexus, implicating the CPe as a major site for drug metabolism in the brain (Ghersi-Egea and Strazielle, 2002). Additionally, CPe expresses high levels of solute carrier (SLC) and ATP-binding cassette proteins responsible for the active transport of drugs, toxins, and other organic proteins out of the CNS, which has many neuro-oncological implications.

Regulators of CSF production

It appears that CSF production occurs at a variable rate. Many innate factors modulating CSF production have been discovered in normal homeostasis and in pathological states. There exists a normal diurnal variation in production, which has been demonstrated in earlier invasive monitoring studies (Hayden et al., 1970) and more recently with MRI. Nighttime secretion may be twofold higher than during waking hours (Nilsson et al., 1992). It appears this phenomenon is autonomically governed as β-adrenergic antagonism abolishes this variation (Nilsson et al., 1994). The choroid plexus receives rich innervation from adrenergic, cholinergic, and peptidergic nerves, containing vasoactive intestinal polypeptide. Sympathetic innervation is inhibitory as sectioning of the superior cervical ganglion increases CSF production and intraventricularly delivered parasympathomimetic agents drastically decrease production (Lindvall and Owman, 1981).

Growing evidence exists for an innate molecular servomechanism modulating CSF production in response to rising pressures. Atrial natriuretic peptide (ANP), arginine vasopressin (AVP), angiotensin-II (AT-II), and fibroblast growth factor-2 (FGF) all appear to play pivotal roles. In animal models, intraventricular infusion of all these substances results in a diminution of CSF production. In human studies, CSF AVP and ANP levels correlate well with increasing ICP but not with ventriculomegaly observed in the absence of increased pressures (Seckl and Lightman, 1988; Tulassay et al., 1990; Yamasaki et al., 1997; Preston et al., 2003) Both also induce a higher ratio of CPe dark cells, the neuroendocrine cell implicated in longer term downregulation of CSF production and lowered chloride conductance (Johanson et al., 1999). CPe expresses receptors for AVP, suggesting a feed-forward mechanism as well receptors for ANG. In contrast to other peripheral tissues, AT-II decreases cerebrovascular resistance, and increases cerebral blood flow. Locally in the CNS, AT-II activates the sympathetic arm of the peripheral nervous system and increases vasopressin release into the blood. Its effects of lowering CSF production appear to be independent of autonomic tone and that CSF AVP promotes AT-II production, representing another positive feedback mechanism (Chodobski et al., 1998). As the BBB and BCSF render the CNS relatively impermeable to circulating AT-II, its vasoconstrictive effects are limited to the choroidal arterioles, representing an additional secondary and peripheral means of lowering CSF formation.

Although the mechanism of increased ANP synthesis and excretion into CSF is unknown, the observed proportional increases in CSF with elevated pressures and the CPe response to it is well documented. In animal models of hydrocephalus, choroidal ANP receptor expression is highly upregulated (Mori et al., 1990) and binding of ANP generates cGMP, leading to altered ion transport and the slowing of CSF production (Johanson et al., 2006). Opposite to AVP, ANP increases choroidal perfusion (Schalk et al., 1992). Taken together, the actions of ANP, AT-II, and AVP act to potently taper CSF production while maintaining CP perfusion and additionally augmenting blood flow to brain tissue at risk for ischaemia in response to elevated ICP. These mechanisms appear to play a significant role in the acute response to raised ICP and ventriculomegaly, but do not seem to be very relevant in chronic hydrocephalic states or those with comparatively lower pressures.

The ependyma

The ependyma does not produce CSF, but provides a relatively porous barrier for communication of parenchymal ECF and ventricular CSF. Ependymal cells lining the ventricular surfaces and that of the spinal central canal possess apical microvilli and motile cilia. They are joined by numerous gap junctions allowing electrochemical coupling between cells and synchrony of ciliary beating along the cranial-caudal axis. Along their luminal border, ependymal cells secrete a glycocalyx rich in sialic acid. Sialic acid is a negatively charged sugar that promotes laminar CSF flow and exerts a repulsive force against coaptation of ependymal surfaces (Jiménez et al., 2014). Micromolar injection of viral neuraminidase into the ventricles of rats, an enzyme degrading sialic acid, causes obliteration of the cerebral aqueduct within four hours (Grondona et al., 1996). This is followed by a sloughing of the majority of ependyma and ventriculomegaly of the lateral and third ventricles. In adult hydrocephalus, the ependyma is extensively thinned or lost entirely and cilia are absent (Bannister and Chapman, 1980). Ependymal denudation, loss of the germinal ependymal zone (the location of neural stem cells) and abnormal neuronal migration has been observed in human fetuses with moderate hydrocephalus and myelomeningocele (Domínguez-Pinos et al., 2005; Sival et al., 2011) A properly functional ependyma is integral to brain development and normal function throughout life and further investigations into its role in health and disease is needed.

Fluid compartments in the CNS

General hydrodynamic theory

The Scottish physicians Alexander Monro (for whom the foramen of Monro gets its name) and his pupil George Kellie are credited with the famous Monro–Kellie hypothesis popularized in the early 1800s. This is sometimes referred to as the Monro–Kellie Doctrine, but this is an erroneous conflation with the Monroe Doctrine, a nineteenth-century American foreign policy doctrine opposing colonialization by European powers. The pressure volume relationships proposed are just as alive today in medical education as they were over 100 years ago. Simply put, the skull is a compartment of fixed volume containing three major components: brain parenchyma, blood, and CSF. The parenchymal compartment consists of neurons, glia, and ECF. The vascular compartment may be divided into two general domains, the arterial and venous compartments. The intracranial subarachnoid space (SAS) can be divided into ventricular and cortical SAS, which can be further subdivided further into increasingly discrete compartments.

The ventricular system consists of the paired lateral, third, and fourth ventricles along with their respective channels of communication. These would be the paired foramen of Monro connecting the third to the lateral ventricles, the aqueduct of Sylvius connecting the third and fourth ventricles, the midline foramen of Magendie and paired lateral foramen of Lushka communicating the fourth ventricle with the cisterna magna and lateral recess of the cerebellopontine angle, respectively. From the cisterna magna in the posterior fossa the ventricular space is thus in communication with the entirety of the cisternal, cortical, and spinal SAS under normal circumstances.

We are comprised of mostly water and water is incompressible. The brain readily withstands compression in the immediate term, but will deform over time. It is evident to any clinician that significant shift of its volume is incompatible with life. In the case of an intracranial mass lesion such an expanding hematoma, CSF from the cranial compartment is shifted to the spinal compartment rapidly and venous blood in the dural venous sinuses partially empties into the systemic venous system to the right atrium. Thus, the spinal compartment acts as a capacitor for CSF volume and pressure while the absorptive mechanisms transfer CSF volume to the venous circulation. The human CNS has great absorptive capacity. CSF is absorbed into the venous circulation in a directly linear relationship with intracranial pressure over time. Eventually once the volume of the intracranial subarachnoid compartment nears exhaustion, intracranial volumes of greater resistances such as the vascular and eventually parenchymal become compromised.

Although the Monro–Kellie hypothesis is traditionally described in regards to an expanding mass lesion, the general principals apply well to the redistribution of fluid volumes in the CNS in all cases. As the volume of any particular compartment in the CNS changes, the volume of the other compartments must compensate commensurately with resistances to fluid conduction in the following order from high to low: arterial, venous, and subarachnoid. Whereas the intracranial space is of fixed volume, the spinal SAS is not. The epidural spinal space between vertebrae contains mostly fat and low-pressure venous plexuses that are quite compressible. Thus, one of the major functions of the spinal SAS is as a capacitance vessel accepting or contributing CSF volume to the cranial subarachnoid spaces.

Impaired hydrodynamics

Over each cardiac cycle, significant shifts in arterial and venous blood volumes occur with a corresponding expansion and contraction of the intracranial tissue volume in response. Thus, a major role of cerebrospinal fluid is as a buffer, shifting from spinal to cranial compartments, protecting the brain from rapid swings in pressure from systole to diastole. This normal flux is conducted through the foramen magnum. Therefore, abnormalities of the skull base and of the brain around the foramen magnum can disrupt efficient flow. Additionally, flow is affected by compartmental compliance. Significant obesity will tend to decrease spinal compliance and restriction to venous outflow from the cranial compartment will decrease compliance in the cranial compartment. Both of these phenomena are observed in idiopathic intracranial hypertension (IIH) formerly called pseudotumor cerebri to varying extents depending on the individual case. Both situations will contribute to higher peak and average ICP fluctuations in addition to higher flow velocities of CSF at the foramen magnum.

Individuals with Chiari I malformation have variable degrees of hindbrain herniation and may have a small posterior fossa. The abnormally low position of the cerebellar tonsils seen in Chiari I may represent an additional resistor in the circuit of CSF flow. This resistance is not exerted at the level of fourth ventricular outflow, but at the foramen magnum. Unimpeded flow from the ventricles to the cortical SAS is maintained and hydrocephalus should not develop unless there exists another, separate pathology driving its development. Dilation of another CSF space is commonly observed though, at the level of the central canal of the spinal cord. Heiss and colleagues have written extensively on the subject, shedding light onto the pathophysiology of syrinx formation in Chiari I (Heiss et al., 2012). High resistance at the foramen magnum to the flow of CSF between spinal and cranial compartments raises CSF flow velocity and local pressure gradients. Exaggerated local subarachnoid pressures at the foramen magnum and high cervical segments drive CSF into the spinal cord parenchyma and central canal additional to the native ependymal formation. Once a syrinx has developed, further enlargement is driven by the differential pressure gradient generated between spinal subarachnoid and central canal spaces with each heartbeat. Establishing unimpeded flow between cranial and spinal SAS will eliminate the syrinx over time and surgical failures largely result from a failure to effectively do so.

Flow of CSF through the cisternal space

An understanding of CSF flow within the cisternal spaces (see **Fig. 92.2**) is best understood beginning with the cisterna magna (CM). The CM is the conduit through which all CSF must flow and within which all CSF mixes. CSF emanating from the ventricular system flows into CM via the single, medial foramen of Magendie, and the paired lateral foramen of Lushka. Many sources have promoted the idea that from here, CSF flows downwards to the spinal SAS and then back upwards to enter the basal cisterns, which then communicate to the cortical SAS. This idea is inconsistent with the anatomy and our understanding of CSF dynamics. The CM is a mixing point connecting CSF compartments allowing equilibration of pressure and free conductance between them. Surgical decompression of the posterior fossa for Chiari 1 malformation and its multiple variations all effectively aim to achieve a similar goal: *The reconstitution of an effectively communicating cisterna magna*. Multiple pathways of outflow exist from the CM:

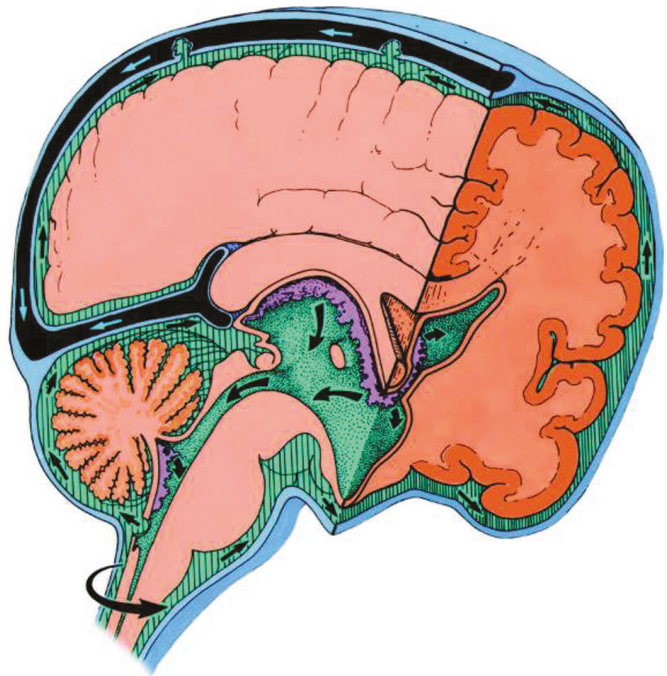

Fig. 92.2 Flow of CSF from the ventricular through the cisternal spaces.
Reproduced from Rekate, H. L., The definition and classification of hydrocephalus: a personal recommendation to stimulate debate, *Cerebrospinal Fluid Research*, Volume 5, Issue 2, Copyright © 2008 Rekate; licensee BioMed Central Ltd.

- Posterior-superiorly over the cerebellum to the quadrigeminal cistern, which then communicates anteriorly to the interpeduncular cistern via the ambient cisterns, wrapping around the midbrain.
- Anteriorly through the cerebellopontine cistern around the pons/medulla to the pontine cistern. Further flow continues superiorly to further discrete, anatomically named cisterns, and finally over the cerebral hemispheres.
- Inferiorly into the spinal SAS and the central canal of the spinal cord.

Knowledge of these cisternal spaces is especially relevant to CSF diversion. In endoscopic third ventriculostomy (ETV), a conduit is created in the floor of the third ventricle and the underlying arachnoid membrane, connecting it to the interpeduncular cistern below. The procedure is an excellent alternative to shunt placement in the case that the anatomical restriction to CSF flow is between the ventricles and the interpeduncular cistern. ETV remains the initial treatment of choice for acquired aqueductal stenosis or triventricular hydrocephalus in later life. Surgical fenestration of the lamina terminalis, the anterior-inferior limit of the third ventricle during aneurysm surgery in the setting of subarachnoid haemorrhage is commonly employed. As the anterior cerebral arteries and their communicator reside within the cistern of the lamina terminalis, access to this location is implied. The efficacy of this procedure is quite logical in that its mechanism is identical to ETV; the third ventricle is connected with a basal cistern.

CSF absorption

Our current understanding of CSF absorption stems from studies of artificial fluid infusion into the SAS performed many decades ago. Even before these experiments it had been long known that intracranial pressure exceeded venous sinus pressure, providing conceptual evidence for a gradient driving CSF absorption. The linear relationship between volumes infused and eliminated across a range of pressures was best initially characterized Weed and Mortensen in canines (Mortensen and Weed, 1934; Weed, 1935). The elimination of CSF into the venous compartment via a passive hydrostatic gradient was most clearly defined by studies carried out in goats by Pappenheimer and colleagues (Pappenheimer et al., 1962). They showed that below a certain threshold of pressure, fluid inflow perfectly matched outflow and thus no net absorption occurred. Once this threshold of pressure had been exceeded, there was a precise linear relationship between CSF pressure and absorption with a maintained total CSF volume. Furthermore, their findings supported previous claims that CSF production was independent of CSF pressure. Rubin et al. (1966) later confirmed these relationships in human adults in addition to defining a maximal elimination capacity of around 1.3 ml/min, or four times the average volume of production. Cutler et al. (Cutler et al., 1968) further corroborated these findings in children, finding an average threshold of absorption of 68 mm/H_20. Figures from their papers are often quoted and depicted in Figure 92.3.

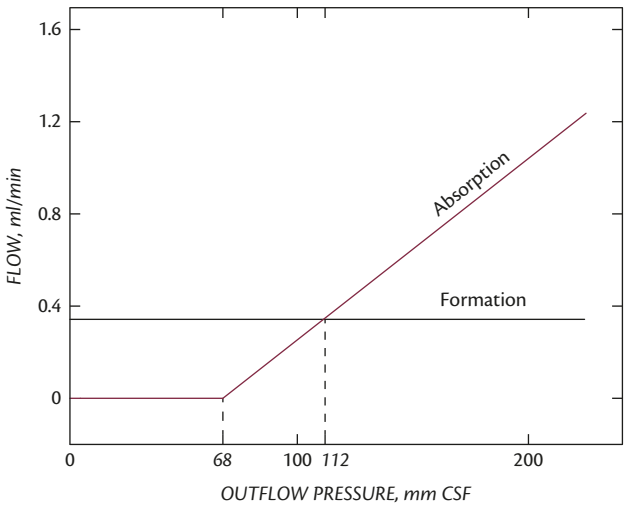

Fig. 92.3 CSF absorption in humans at various pressures.

Superimposed regression lines for CSF formation and absorption as a function of outflow pressure. The intercept at 112 mm indicates the pressure at which formation and absorption are equal. The pressure at which absorption is zero is also indicated.

The arachnoid granulations

As early as the eighteenth century, anatomists had proposed a secretory role of arachnoid granulations (AGs). These assumptions were bolstered by the observations of Luschka and Trolard that the granulations were large villi of arachnoid that protruded through the dura into the venous sinuses. Weed had published extensively in the early twentieth century that the likely mechanism of absorption occurred via an osmotic and hydrostatic gradient across semipermeable blind ended out-pouchings of arachnoid. Although Cushing had earlier proposed that these enlarged diverticulae represented biological one-way valves, it would be half a century until he was proven right. Welch and associates were the first to observe primate AG fixed while being perfused at varying pressures with the light microscope. They observed flattening of primate villi at negative pressures and a complex labyrinth of tubules, which allowed passage of particles up to several microns (Welch and Friedman, 1960; Welch and Pollay, 1961). Later, with the use of electron microscopy, unidirectional endothelial cell vacuolization leading to pore formation was demonstrated (Gómez et al., 1973; Tripathi, 1974) and that the pressure differential applied was proportional to the degree of vacuole/pore formation depicted in Figure 92.4 (Levine et al., 1982). Together, these discoveries provided the anatomical substrate to validate the absorptive behaviours of CSF documented so many years before. When taken in whole, these absorptive behaviours are analogous to the function of a slit valve. A slit valve has a set opening pressure under which no fluid flows. Once the opening pressure has been exceeded, there is a direct linear relationship to pressure and fluid outflow. The normal homeostatic arrangement allows CSF absorption to match production over time. Factors such as positional change or fluctuations in cerebral blood volume may temporarily tip the scales in one direction in a compensatory manner, but a steady circulating volume is maintained over the longer term.

Alternative routes of CSF absorption

It is traditionally taught that the AG along the superior sagittal sinus are solely responsible for CSF absorption. This appears to be only partially true. The slit valve behaviour of CSF bulk flow likely represents a combination of absorptive processes. CSF is clearly absorbed

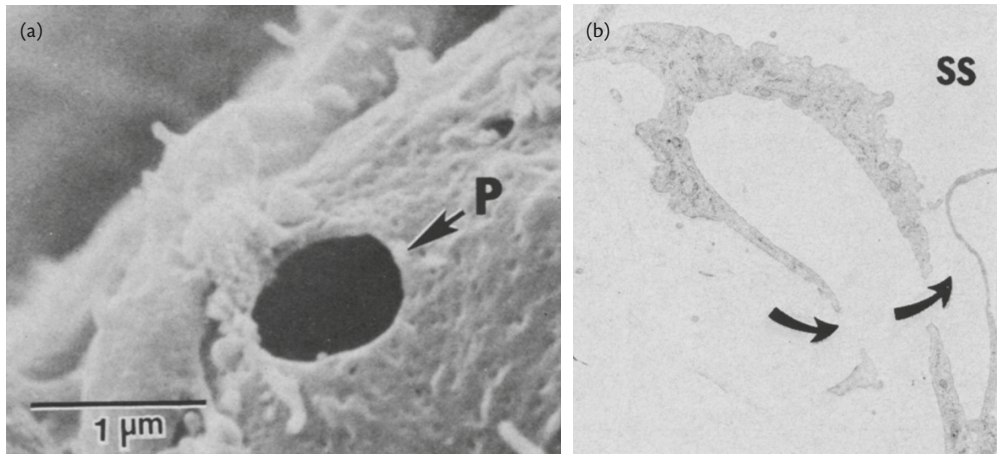

Fig. 92.4 Electron microscopy of the arachnoid granulations.
Electron micrographs showing pore formation in arachnoid villi protruding into the venous sinus under conditions of artificial CSF infusion at high pressure.

via lymphatic, spinal, and nerve root pathways in addition to the arachnoid villi. As early as 1875, Key and Retzius had documented cadaveric subarachnoid injection of trypan blue tracer accumulation in the AG as well as the cervical lymph nodes. These findings were confirmed by Weed and colleagues, and further clarified by many researchers throughout the twentieth century. These works constitute an overwhelming body of evidence supporting alternative pathways of CSF absorption other that the AG. The bulk of our knowledge arises from animal investigations. Thus, it is important to conceptualize human CSF absorption through our understanding of absorption across the animal phyla studied. Macroscopic AGs do not exist in rodents, rabbits, or cats. In larger mammals such as dogs and ruminants, they are less developed and fewer in number than in humans. Only in primates do we observe arachnoid villi of comparable size and number, albeit less than those observed in humans. In evolutionary terms, as brain size and complexity has increased, so has proportional CSF production. This is coupled with a commensurate reliance on more developed and specialized AGs. In addition to these anatomical observations, a proportional increase in CSF conductance is observed experimentally across phyla with the greatest values observed in Mann (Mann et al., 1978).

It seems that as mammalian brains have grown in size and complexity, CSF absorption has moved from primarily perineural and lymphatic routes of absorption to a strategy more dependent on excretion into the venous circulation via arachnoid villi. Although specialized AG endow humans with a great absorptive capacity, extra-arachnoidal elimination still likely plays a large role. Together, these comprise a dual outflow system. Arachnoid villi only appear microscopically around the time of birth in humans and do not contribute significantly to CSF absorption until late infancy or early toddlerhood (Gómez et al., 1982). It may be the case that during fetal development, and into early infancy a more primitive phenotype of CSF absorption is maintained. This primitive configuration at the beginning of life would rely heavily on extra-arachnoidal mechanisms of CSF absorption and much less so on AGs (Oi and Di Rocco, 2006). As the nervous system grows and matures, the adult phenotype is realized relying more heavily on arachnoid villi as shown in Figure 92.5. This phenomenon may also play a role in the high failure rate of ETV observed in the neonatal and early infantile period.

Pressure-volume curves generated over time in hydrocephalic patients as compared to normal subjects also support the dual outflow hypothesis. In a normal individual, one smooth semi-logarithmic pressure-volume curve is generated during an artificial CSF infusion study. Several published investigations have demonstrated a curve with two distinct components representing different absorptive behaviours at high or low rates of infusion likely reflecting distinct absorptive pathways (Lorenzo et al., 1970; Nelson and Goodman, 1971; Sokolowski, 1976). The presence of AV along the spinal roots has been well documented in sheep, dogs, and primates (Welch and Pollay, 1963; Gómez et al., 1974). In humans, AV are present at most levels and are juxtaposed or protrude directly into radicular veins (Tubbs et al., 2007). Upon physical separation of spinal and cranial compartments, Marmarou et al. (1975) demonstrated spinal AV in cats absorbed 15% of total CSF production and accounted for 32% of the total compliance. This number increases to about 25% of total absorption in sheep (Bozanovic-Sosic et al., 2001). In humans it has been estimated that at rest nearly 40% of absorption takes place in the spinal space and this increases to 75% with activity (Edsbagge et al., 2004). Robust evidence exists for CSF outflow via nasal lymphatics through the olfactory perineural pathway, optic nerves, and other cranial nerves in animals, but evidence is lacking in humans. There is little doubt that this absorptive pathway does function in man to some extent, but unfortunately, no method exists to date that would allow us to accurately quantify the actual contribution of perineural lymphatic drainage of CSF in humans.

Absorption of CSF via a parenchymal route is a controversial topic. There have been many recent investigations into parenchymal or glymphatic reabsorption of CSF that have some significant merit. Additionally, there are clinical observations supporting this hypothesis that are difficult to ignore. In patients with obstruction of the cerebral aqueduct, the rate of the resultant ventricular dilatation is far less than the normal CSF production (Bering and Sato, 1963) and this is supported in multiple animal models. In primates, when the cerebral aqueduct is blocked, initially the supratentorial ventricles enlarge rapidly. After some time, this enlargement slows and could not possibly reflect the total production of CSF within the ventricle (Milhorat et al., 1970). There has been much recent debate stemming from models of CSF flow obtained by cine-MRI, some of

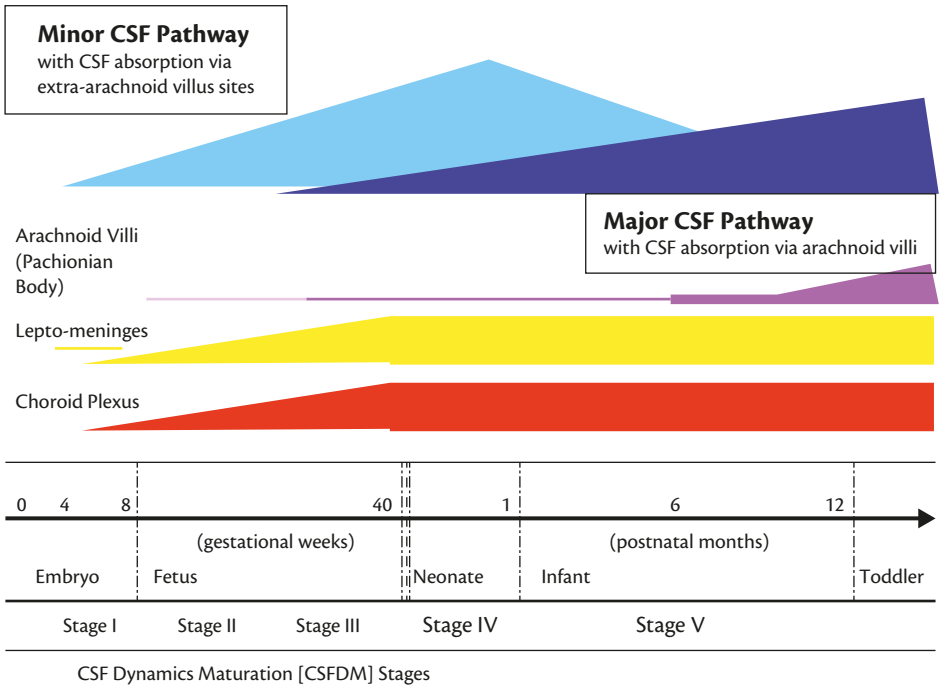

Fig. 92.5 Proposed development of CSF absorptive processes with age.

Proposed sequence of development of CSF productive and absorptive pathways in the first year of life by Oi and colleagues.

which demonstrate reversal of CSF flow with terminal absorption occurring within the ventricles. The findings are based on flow estimates derived from phase contrast MRI that depends on proprietary software, tight calibration, digital subtraction, precise voxel selection, and highly derived mathematical modelling. All these factors draw into question the validity of these results in addition to the lack of validation with an alternative method of flow beyond MRI.

We can accept that a substantial proportion of CSF volume, probably around one-third is derived from parenchymal ECF, although direct methods to precisely quantify this contribution have yet to be developed. There has been much recent activity in the literature attempting to characterize absorption of CSF by brain parenchyma. The ability to quantify net absorption through the interstitium, if it does become a major route, is even more problematic. Studies have demonstrated net flow of various tracer compounds from SAS through interstitial spaces via arteriolar or venular microcirculations within the Virchow-Robins spaces. Whether the transport of these tracers truly represents net or bulk flow of fluid is yet to be determined. The major thorn in the side of these theories is that they require significant violations in how we understand the blood–brain barrier. This relatively impermeable barrier tightly and actively regulates solute concentrations within the parenchymal microenvironment. Solutes are actively transported which, in turn, strictly regulate the net flow of water. We have yet to establish a mechanism of ion secretion in any direction *other* than from plasma into the CSF or interstitial space. Although extracellular fluid reabsorption at the capillary level can be enhanced by hydrostatic pressure (ICP), without a mechanism to excrete solutes out of the parenchyma, it would be impossible to maintain a net flux of water from brain tissue into the systemic circulation for more than a few minutes.

One important exception to the aforementioned physiology exists in the phenomenon of periventricular oedema observed in many hydrocephalic states, referred to as transependymal flow. Hydrostatic pressure drives water across the ependyma into the extracellular space of the white matter surrounding the ventricles, lowering its colloid osmotic pressure. This creates an osmotic gradient promoting the net flow of extracellular water into the vascular space capable of conducting a large volume of excess fluid. Aquaporin-4 (AQP-4) is heavily expressed along the astrocytic foot processes enveloping cerebral blood vessels, an integral component of the BBB. There exists a large body of research demonstrating the function of AQP-4 in animal models of hydrocephalus. AQP-4 is integral for ependymal integrity (Li et al., 2009). AQP-4 is upregulated in both multiple experimental hydrocephalus models and in hydrocephalic patients (Castañeyra-Ruiz et al., 2013; Skjolding et al., 2013). Furthermore, the experimental hydrocephalus induced in AQP-4 knock-out mice is far worse than in normal mice. Mice lacking AQP-4 have less oedema and recover better than controls in models of cytotoxic oedema such as TBI and stroke. In models of vasogenic oedema such as tumour or abscess, the knock-out mice have more oedema and fair much poorer than controls. These findings highlight the central role of AQP-4 in parenchymal water regulation. AQP-4 represents a promising pharmacological target in the treatment of a wide spectrum of neurological disorders.

Development of ventriculomegaly

Although the development or resolution of ventriculomegaly seems intuitive on a superficial level, a deeper exploration into the

mechanics governing relative compartmental sizes presents major theoretical dilemmas. If the brain and vascular volumes are to remain stable, which we can assume it must over the short term, how do we account for a major increase in the ventricular spaces? How can we account for the rapid decrease in ventricular size after ventriculostomy or shunt placement without the head becoming smaller? The answer cannot be that we are violating the law of conservation of mass.

These questions can be explained by the redistribution of the same initial volume of cerebrospinal fluid to a different location in the SAS, namely the ill-defined cortical SAS. Normally only 50–60 ml of a total 130–150 ml of CSF occupies the ventricular space. As we know, this volume can fluctuate widely in disease and with age. A rapid change in ventricular volume must be accompanied by a commensurate adjustment in the cortical and cisternal SAS if relative brain and vascular compartments are to be maintained. Volumetric changes in the cisternal and cortical SAS are difficult to appreciate with current imaging technologies. Determination of its normal volume in the absence of disease remains elusive. Thus, these relationships have been underappreciated and misunderstood by most clinicians. **Figure 92.6** demonstrates a spherical theoretical model of the ventricular and cortical SAS. An increase of only 2 mm in thickness of the cortical SAS is able to compensate for a 104 cc decrease in ventricular volume. This cryptic ability of the cortical SAS to accept CSF volume is likely further enhanced by brain sulci and the perivascular, or Virchow-Robins spaces.

Inappropriately excessive drainage of the ventricles will lead to subdural hygroma, which is in effect, a massive enlargement of the cortical subarachnoid space to compensate for overzealous shunting. If production and spinal reserves of CSF cannot match drainage, tearing of bridging veins and extravasation of blood into the hygroma, (conversion to a subdural hematoma or SDH) will account for the volume. As the ventricles present a lesser resistance to drainage then the complex multicompartmental cisternal spaces, excessive CSF removal from the lumbar spaces will behave quite similarly. This is pertinent to the discussion of hydrocephalus developing in the setting of very low to negative pressures. The missed diagnosis of spinal CSF fistulae resulting in hygroma or chronic SDH can be a disaster as progressively aggressive surgeries are carried out to drain the collection.

Similarly, progressively aggressive surgeries for shunt malfunction in a patient with an undiagnosed CSF fistula can be equally harmful. When CSF diversion was initially required as a result of high resistance to flow between ventricular and cortical SAS (i.e. 'obstructive' HCP), a CSF leak at any location will preferentially drain the cortical/cisternal SAS. A pressure gradient, denudation of cortical/cisternal SAS volume and continued ventricular CSF production will drive ventriculomegaly. This situation gives the appearance of shunt malfunction with a perfectly functional shunt; progressive ventriculomegaly is able to continue at pressures below the opening pressure of the valve. In this case, placement of a ventriculostomy catheter will yield CSF only when drained at paradoxically low or negative pressures. This rare situation is well documented in the neurosurgical literature and is definitively treated by identification and repair of the CSF leak. Further highlighting the interaction between intracranial fluid compartments, Rekate et al. (2008) have documented in multiple instances that the application of a gentle cervical tourniquet, in the form of an elastic bandage, will rapidly

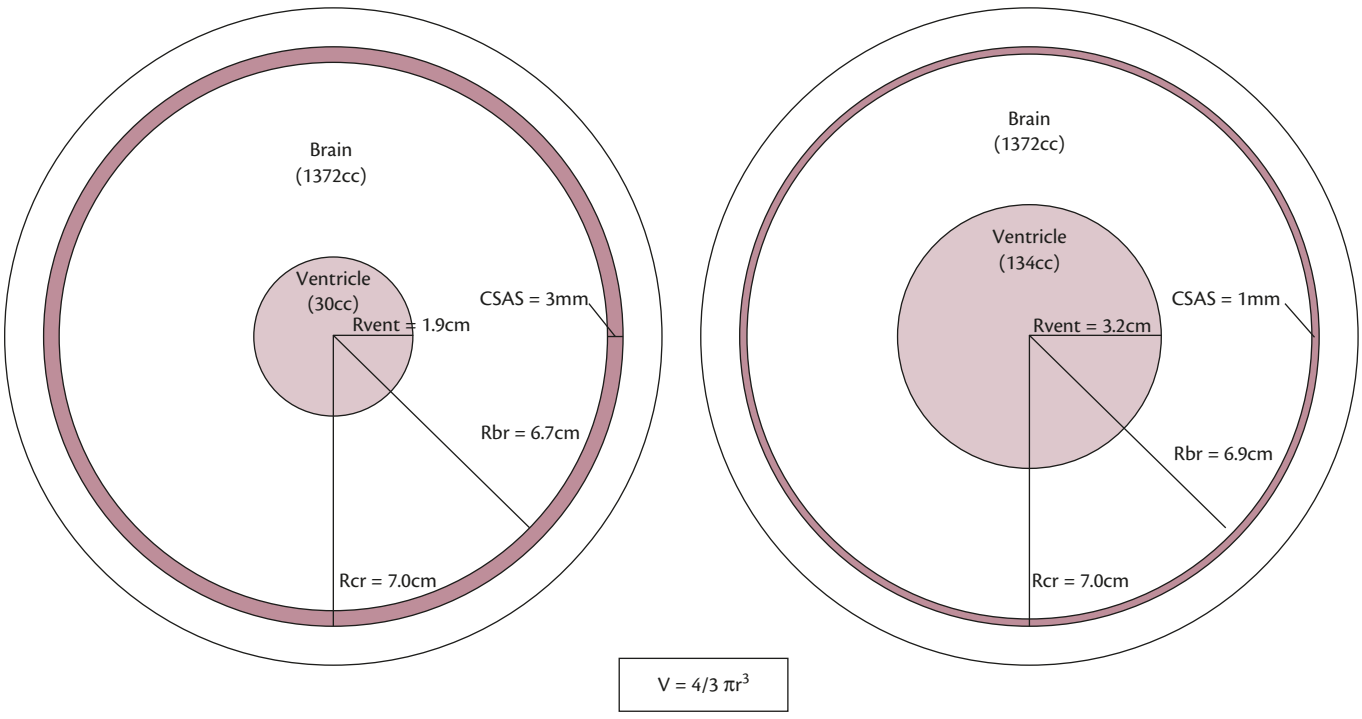

Fig. 92.6 Relationship between cortical subarachnoid and ventricular volumes.

Left: Representation of normal ventricular volume (V) in a normal or adequately shunt-treated individual. Right: Representation of the visual change in the size of the ventricular system when the thickness of the cortical subarachnoid space is decreased from 3 mm to 1 mm. In this illustration, the volume of the brain remains constant.

reverse ventriculomegaly and restore consciousness in cases such as these. Compression of the venous structures in the neck functioned to increase cerebral blood volume in the brain, increasing brain turgor, or stiffness. The addition of volume to the intracranial cavity and lowering of brain compliance allowed for sufficient pressure generation in excess of the shunt's opening pressure. This allowed temporary alleviation of the patient's symptoms attributable to ventriculomegaly until definitive management of the fistula could be obtained.

Classification of hydrocephalic states by point of obstruction

The traditional classification of *obstructive* or *communicating* poorly describes the pathophysiology leading to the various hydrocephalic states (see **Box 92.1**). In fact, all forms of hydrocephalus are obstructive by nature. Within the circuit of CSF flow, the location of a resistance defines the patterns ventriculomegaly observed. Here, we propose a classification based upon the location of the resistive element in the circuit from most proximal to distal in terms of CSF production and terminal absorption. The paired lateral ventricles contribute the greatest volume of CSF and contain the majority of choroid plexus shared among the four ventricles. Thus, this compartment is the driver of bulk CSF flow in its journey to more distal sites of absorption. Beginning at the most proximal, the lateral ventricles themselves can become obstructed from within. Mass effect onto the lateral ventricle by tumour, oedema, or hematoma may isolate choroid plexus, commonly in the temporal horn causing progressive enlargement of this 'trapped' ventricular portion. This can be potentially lethal, leading to uncal herniation. Scarring and loculations within the ventricular system can also create isolated CSF compartments leading to asymmetrical enlargement of portions of the ventricular system.

Several pathologies may obstruct the foramen(s) of Monro leading to progressive dilatation of only one or both lateral ventricles. A functional obstruction secondary to overdrainage of a single lateral ventricle has been described. Negative pressure draws the septum pellucidum over the ipsilateral caudate head, obstructing the foramen of Monro. The suction created by the shunt maintains isolation of the shunted ventricle and the initial pathology continues unabated, driving further enlargement of the un-shunted compartments. Another consequence of long-term overdrainage is coaptation or scarring together of ependymal linings. This may occur within the third ventricle leading to lateral ventriculomegaly or within the cerebral aqueduct, causing enlargement of all three supratentorial ventricles. Although triventricular hydrocephalus has been traditionally viewed as the *sine qua non* of aqueductal stenosis, reconstitution of the aqueduct has been demonstrated in some cases after shunting or ETV, demonstrating a functional obstruction such as compression by the enlarged posterior portions of the lateral ventricles (Rekate, 2007).

Dandy-Walker cysts or other pathologies filling the fourth ventricle actually represent an obstruction to the fourth ventricular outflow while giving the appearance of aqueductal stenosis. Fenestration of the cyst or resection of the pathology may subsequently restore a fourth ventricular space and return of flow through the cerebral aqueduct. This is one of many strategies to achieve shunt removal in a previously shunt dependent patient, or avoidance of initial shunt placement altogether. Chiari I malformation may lead to obstruction of the foramen of Magendie, but the degree of tonsillar herniation alone is not sufficient to cause obstruction of the bilateral foraminae of Lushka. Therefore, many Chiari I malformations are secondary effects of a primary hydrocephalus, not vice-versa. Conversely, Chiari II malformation causes obstruction of fourth ventricular outflow and enlargement of all ventricles. Mixing of amniotic fluid and CSF via an open neural tube defect results in dense scarring and adhesions in the basal cisterns. Combining this with a greater degree of downward herniation, ventricular spaces are functionally isolated from the spinal and cortical subarachnoid spaces as evidenced by the extremely high rate of ventricular shunting needed in this population and high failure rate of ETV. Overall, meningitis is likely the most common cause of chronic fourth ventricular outflow obstruction but is usually more amenable to ETV.

Obstruction of flow within the cisternal spaces will lead to enlargement of all ventricular spaces and is the presumed aetiology of a majority of NPH cases. Some conclusions may be drawn about the site of obstruction from the appearance of the extraventricular CSF spaces on neuroimaging. This information can be useful in selecting the right patients for the most appropriate procedure. Aneurysmal subarachnoid haemorrhage (SAH) resulting in hydrocephalus is similar in that blood products physically impede flow through the cisternal space and cause scarring over the longer term. In extremely rare situations, individual patients may produce an excessive quantity of CSF. This can occur spontaneously or in the setting of a choroid plexus papilloma. If production exceeds the absorptive capacities of the collective CSF outflow systems, ventriculomegaly may develop. Therefore, the obstruction can be viewed as occurring at the most distal point, such as the AGs.

The utility of ETV in treating NPH is unclear secondary to mixed results from multiple case series. Generally speaking, as we better define the mechanisms behind most diseases, it becomes evident that there are multiple, distinct pathophysiologies leading to a similar clinical manifestation. NPH is a perfect example of this. The disease is largely defined by ventriculomegaly disproportionate

Box 92.1 Classification of hydrocephalus by point of obstruction

Lateral ventricles
Isolation of a portion or 'trapping' of the lateral ventricle by congenital lesion, scarring, IVH, or mass

Foramen of Monroe
Colloid cyst, ventricular tumours, congenital anomalies, and functional obstruction*

Third ventricular outflow
Aqueductal stenosis, coaptation of third ventricular ependyma*, pineal tumours, focal webbing, ventriculomegaly with functional obstruction

Fourth ventricular outflow
Meningitis, Chiari 2, Dandy-Walker, tumours

Basal cisterns
NPH, SAH/IVH, arachnoid cyst, meningitis

Terminal absorption
Venous hypertension in infancy (vein of Galen malformation), choroid plexus papilloma, Hypo-vitainosis A

*Secondary to overdrainage.

to cortical atrophy with a characteristic constellation of symptoms. There is growing evidence that what we call NPH is actually a spectrum ranging from late-onset aqueductal stenosis, restrictive arachnoid membranes from within the proximal basal cisterns to the most distal cortical SAS, or progression/decompensation of an arrested infantile hydrocephalic state in late adulthood. We can deduce that some of these pathologies would respond to ETV and others would not depending on the site of restriction to flow which is consistent with the observed clinical results to date. As NPH patients are more precisely classified in regard to the nature and location of their obstruction, so will their treatments with increasing degrees of success.

Infantile hydrocephalus

The physics governing the development of hydrocephalus during the first year of life are unique. Neonates are relatively protected from elevated ICP, as their skulls are distensible. The younger an infant is, the less force is required to increase the volume of the head. As the cranial sutures become progressively interdigitated and the fontanels close, elevations in intracranial pressure have less of an effect on head size or intracranial volume. As discussed previously, CSF absorption mirrors the function of a slit valve, requiring CSF pressure to rise above a certain threshold before net absorption can occur. In newborns, with the inward force created by the cartilaginous plates that will become the bony neurocranium, scalp and ambient barometric pressure generate just enough pressure for absorption to occur. Neonatal hydrocephalus behaves as though there is an inherently higher resistance to CSF outflow, or a slit valve with a greater opening pressure. In this case, the tensile properties of the skull and atmosphere are unable to overcome the resistance to CSF absorption, resulting in distention of the intracranial compartment, or head growth. In general, brain parenchyma is probably not lost, but pushed outward and stretched mirroring the increases in cranial volume. After shunt insertion in a hydrocephalic infant, the change, or more specifically, the rate of change in ventricular size is probably best characterized by the degree of articulation of the neurocranium and the rate of brain growth. It may take many months to realize a small or normal sized ventricular system as the growth of brain tissue replaces what was excess CSF volume after a few months of life render the skull unable to collapse. Conversely, in the neonatal period and especially in the premature, sinking of the fontanel, and overlapping of the sutures can normalize ventricular volume nearly instantaneously.

Although quite controversial, the late paediatric neurosurgeon Fred Epstein reported successes in treating infantile hydrocephalus with compressive head wrapping as opposed to shunting (Epstein et al., 1974). Head compression allowed ICP to rise above the opening pressure of absorptive mechanism whereas without compression, CSF pressures never reached the levels necessary for CSF absorption. Although the neurosurgical community never adopted this treatment, Epstein claimed to have successfully treated 8/10 infants, avoiding shunt placement. ETV success is inversely related to age in infancy, with poor efficacy in patients less than 6 months of age. The same physical properties explain why the same procedure for an identical pathology, say aqueductal stenosis, tends to be successful in a 2-year-old, but more often fails in a neonate. Although a conduit for efficient CSF flow is created between the supratentorial ventricles and basal cisterns, there exists a higher resistance to CSF absorption distal to the artificial stoma. Again, the compliant neonatal cranium is unable to generate the forces required for adequate CSF absorption. Ventriculomegaly persists and pathological head circumferences continue despite a working ETV. The same anatomical arrangement also explains the hydrocephalus resultant from intracranial venous hypertension in infancy. The elevated venous pressures seen in cases of vein of Galen malformation lead to hydrocephalus in infants as CSF pressures in the cortical SAS must exceed venous ones in excess of roughly 5 cm of water. Thus, a situation that would lead to the development of IIH in an adult gives rise to macrocephaly and ventriculomegaly in the neonate.

Conclusions

We hope it is apparent to the reader that hydrocephalus is not a single disease, but actually a grouping of a myriad of conditions resulting in ventriculomegaly. The clinical decision is all too often to place a ventricular shunt without a careful consideration of an individual's unique anatomy and physiology. This is akin to the expression: 'To a hammer, everything is a nail'. We must remember that to the patient, a shunt may be a lifelong sentence. The neurosurgeon routinely consigns patients to a fate relying on mechanical devices that are destined to fail and cannot recapitulate normal physiology. The understanding of normal CSF physiology and its derangements in disease is important to the clinician to best manage and appropriate treat patients. To those of us in the neurosciences, hydrocephalus is a common problem with a seemingly limited array of management tools. It is clear that we have yet to fully appreciate the amazing complexity of the CSF dynamics. We have a responsibility to innovate in the arena CSF diversion technologies and in the development of pharmacological agents capable of modulating CSF dynamics. This is the next horizon in hydrocephalus research that our patients and their families eagerly await which is unfortunately, long overdue.

Shunt technology and endoscopic ventricular surgery

Ian K. Pople and William Singleton

Introduction

The management of cerebrospinal fluid (CSF) disorders is a complex clinical science, requiring a detailed understanding of CSF physiology in both the normal and diseased brain. Successful treatment requires a comprehensive knowledge of the available shunt types, their similarities, differences, and idiosyncrasies. The rapid development of endoscopic neurosurgical techniques makes treating this group of patients without a shunt often a real possibility, and arguably is now a core neurosurgical skill. In this chapter we will summarize CSF physiology in the normal state, and explain the principles of CSF diversion before going on to describe the various shunt types available. A section will be devoted to endoscopic CSF diversion techniques, including a detailed explanation of third ventriculostomy.

CSF physiology

CSF is thought to have four main functions:

1. Buoyancy: thus reducing the weight of the brain by 'floating' it in fluid
2. Removal of large and hydrophilic waste metabolites
3. Circulation and transfer of neuropeptides within the central nervous system (CNS): particularly important during fetal and early infant development
4. Maintenance of cellular homeostasis within the CNS

CSF is principally produced from choroid plexus within the ventricular system, though approximately a third of the circulating volume is thought to be produced from the pia-ependyma of the ventricular wall. With each arterial pulse wave, CSF circulates from the lateral ventricles, though the foramen of Monro to the third ventricle. It then passes to the fourth ventricle via the aqueduct of Sylvius before entering the infratentorial cisterns and spinal subarachnoid space laterally via the two foraminae of Luschka and medially through the foramen of Magendie.

Traditional teaching says that the majority of CSF absorption occurs at the arachnoid granulations located at the major venous sinuses. This is probably the case for a proportion of circulating CSF; however, there is a growing body of evidence that under normal physiological conditions, a large proportion of CSF is re-absorbed through the perivascular Virchow-Robin spaces within the brain parenchyma into draining lymphatics. Water from CSF is also actively transported into capillaries and astrocyte end-feet within the brain via aquaporin channels (Brinker et al., 2014). These discoveries explain how acute hydrocephalus is often associated with periventricular oedema/lucency on CT and MR imaging.

Normal CSF dynamics

In normal adults CSF occupies approximately 9% of intracranial space. Normal children have smaller ventricles and a smaller amount of intracranial CSF in relation to brain and blood. The pressure/dynamics of CSF circulation are controlled by three elements:

1. The rate of CSF production
2. Ventricular compliance
3. CSF absorption

In normal circumstances CSF is produced at a constant rate regardless of intracranial pressure (ICP). The elasticity of the ventricles and brain decreases as the CSF volume increases. CSF absorption or resistance to outflow (assuming that most CSF is absorbed at the arachnoid villi) is defined as the difference between the pressure of CSF at the arachnoid villi and the pressure from the arachnoid villi to the dural sinus. In the normal resting state, ICP equals CSF pressure. ICP can therefore be defined as:

$$ICP = (I_F \times R_O) + R_D.$$

Where I_F equals the rate of CSF production, R_o equals resistance to CSF absorption and R_D equals dural sinus pressure. Therefore, from a CSF dynamics perspective, ICP can rise as a consequence of increased CSF production, increased resistance to CSF absorption or an increase in dural sinus pressure. The equation explains how dural sinus occlusion has a direct effect on CSF pressure and ICP. It also shows how intracranial elastance ($\Delta P/\Delta V$) is related to

the difference between the resistance to CSF outflow and dural sinus pressure. Elastance may be reduced by anything that restricts intracranial space or decreases CSF absorption, (including ventricular or cisternal CSF obstruction). All of these will increase the amplitude of the CSF pulse wave and cause a subsequent rise in ICP (Marmarou et al., 1975; Marmarou et al., 1978; Shapiro et al., 1980).

Principles of CSF shunting and CSF diversion

Hydrocephalus is a condition characterized by an increase in the size of the CSF spaces at the expense of brain. This is often associated with a rise in intracranial pressure, which left untreated can result in death or significant disability. The principle treatment of hydrocephalus is surgical CSF diversion, most commonly with the use of a shunt device.

Shunt hydrodynamics

Familiarity with the relationship between pressure and flow is an integral part of choosing the most appropriate device when treating a patient (Chari et al., 2014). CSF flow through a shunt is dependent on various factors. These include the intraventricular pressure (IVP), the hydrostatic pressure (p), the valve's opening pressure (OPV) and the pressure within the cavity in which the shunt is placed (e.g. intra-abdominal pressure, IAP). Therefore, the pressure gradient (ΔP) through a standard ventriculoperitoneal shunt can be defined as:

$$\Delta P = IVP + p - OPV - IAP.$$

Where hydrostatic pressure (p) is the product of the height of the fluid column, the density of CSF, and the gravitational force. In any given patient, the OPV is a constant for the particular system chosen whereas IVP and IAP may fluctuate depending on posture. The main variable that contributes to hydrostatic pressure is the height of the column of fluid (i.e. length of shunt tubing), therefore shortening the distal shunt tube will affect the CSF flow.

The flow of CSF (F) through a tube is equivalent to the pressure gradient, ΔP, divided by the resistance in the tube (R_T) and valve (R_V):

$$F = \Delta P / \left(R_T + R_V\right).$$

The resistance of the tube can be calculated using Poiseuille's law and is a constant for the particular system chosen, as long as the shunt is not shortened by the surgeon. The determinants of CSF flow within a shunt will therefore be regulated by the following:

1. The underlying condition and IVP
2. The patient's position
3. The resistance provided by the shunt system

Siphoning

In normal people the difference in pressure between the arachnoid granulation and venous sinuses (the principle CSF outflow tract) is not affected by posture. However, in patients with a shunt there is a rapid increase in flow rate through the shunt when they sit/stand up as the difference between intraventricular pressure and the pressure at the distal end of the shunt increases. This will lead to siphoning of CSF from the head and overdrainage (Petrella et al., 2008; Farahmand et al., 2015). Clinically this will often present with symptoms that occur when the patient moves from a recumbent to an upright position (Table 93.1). Long-term overdrainage from a shunt system is thought to be significant risk factor in the development of slit ventricle syndrome.

Table 93.1 Symptoms/signs of shunt overdrainage

Symptoms	Signs (clinical and radiological)
Headaches and nausea on standing (resolved when recumbent)	Cranial nerve palsy (in severe cases)
Tinnitus and vertigo on standing (resolved when recumbent)	Acquired Chiari malformation
Drowsiness and coma (severe cases)	Subdural collections
	Slit-like/collapsed ventricles

Shunt types

The choice of shunt position

In its most simple form, a shunt is a surgically implanted tube that diverts CSF from the ventricular compartment to another body cavity or CSF compartment. Lumbar shunts shift CSF from the lumbar theca. Most commonly the site of drainage is the abdomen, right atrium, or pleura. Other sites of drainage are summarized in Table 93.2 along with their advantages and disadvantages. The proximal shunt catheter is most commonly placed in the ventricle through either a frontal or occipitoparietal burr hole. These two approaches are associated with several advantages or disadvantages, but are usually chosen through surgeon preference (Table 93.2). There is no randomized study to show one technique is superior to any other. The adoption of intraoperative image guidance as a routine tool in modern neurosurgery has been advocated by some surgeons to reduce the risk of misplaced or suboptimally positioned catheters within the ventricle (Flannery et al., 2014).

Valve technology

There are two main types of shunt valve: those that regulate CSF flow (flow-regulated valves), and those that activate at a set CSF pressure—differential pressure valves (Czosnyka et al., 2002). Differential pressure valves may be a simple valve that opens once the IVP equals the set opening pressure of the valve, or more sophisticated gravitational or adjustable systems. Most of the data on efficacy of various valves are reported by proponents of the device and no randomized controlled trials are available to compare these devices in full. The only randomized trial data to date did not show any clinical difference in shunt survival between three valve types; a 'normal' differential pressure valve, a differential pressure valve with an antisiphon device (Delta Valve, Medtronic) and the Orbis-Sigma (Cordis) flow-controlled valve (Drake et al., 1998). It is therefore

Table 93.2 Sites of proximal shunt position, sites of distal shunt position and their advantages and disadvantages

Shunt position	Advantage	Disadvantage
Proximal catheter		
Frontal horn	• Anatomy of ventricular catheterization more predictable (when not using image guidance): especially in patients with small ventricles. • Less choroid plexus.	• Requires an additional cranial incision for valve insertion (usually inserted in-line to the shunt behind the ipsilateral pinna) • Possible higher short-term ventricular catheter blockage rate • Often requires movement of the head intraoperatively
Occipital horn	• One surgical position during shunt insertion • Longer ventricular portion of catheter—may reduce chance of early blockage • Only requires a single cranial incision and simpler to revise	• Anatomy of ventricular catheterization more variable (when not using image guidance)
Lumbar theca	• Avoids need of ventricular shunt in patients with very small ventricles (For example in idiopathic intracranial hypertension)	• Risk of postural overdrainage and development of acquired Chiari I malformation • Requires addition of more complex gravitational valve unit.
Distal catheter		
Peritoneum	• Large cavity that absorbs fluid readily • Easy to access • Core neurosurgical skill and widely practised	• May limit shunt function in patients with high intra-abdominal pressure • Surgically challenging in patients with multiple intra-abdominal adhesions • Reduced CSF absorption in patients with a high CSF protein (CSF 'ascites')
Right atrium	• Distal shunt occlusion possibly less likely than in ventriculoperitoneal and ventriculo-pleural shunts • A good option in patients with high CSF protein, or recurrent distal shunt malfunction using the peritoneum or pleura	• Shunt nephritis • Shunt revision may be surgically challenging • Not a routine technique – requires specialist skills • Shunt infection may have significant systemic manifestations – such as endocarditis • Theoretical risk of arrhythmia
Pleura	• Easy to access surgically	• Capacity for CSF absorption through the pleura is less than in the peritoneum • Negative intrathoracic pressure during inspiration may increase risk of siphoning • Reduced CSF absorption in patients with a high CSF protein
CSF cistern (cisterna magna) 'Torkildsen shunt'	• 'Bypasses' ventricular obstruction without draining CSF away from CNS: now largely superseded by endoscopic techniques	• Technically more challenging than standard techniques (not routinely practised)
Bladder	• None in modern practice (historical technique)	• Infection • Visceral injury • Challenging revision surgery
Gall bladder	• None in modern practice (historical technique)	• Infection • Visceral injury • Challenging revision surgery

important for the treating physician to understand the properties of these shunt valves and choose the most appropriate system on an individual basis.

Flow-regulated valves

Although termed 'flow-regulated' these valve systems do not measure flow but utilize variable resistance to control the flow rate of CSF to a constant range of flow rates. One example is the Integra OSV II® system. These valves consist of a synthetic ruby pin within a moveable ring. They will work as a differential pressure valve until the ICP is high enough to displace the ruby pin downwards, reducing the outflow aperture, and thus increasing resistance to flow. This allows a constant flow rate at a range of ICP. With further increases in ICP, the moveable ring becomes displaced downwards, opening the aperture and reducing the resistance to flow (Fig. 93.1).

This type of valve may be of benefit in patients with siphoning and overdrainage problems or in those with a high risk of developing slit ventricle syndrome. Current data has shown a benefit in improving symptoms of low ICP but no difference in their revision rates compared to other types of valves (Drake et al., 1998; Hanlo et al., 2003). There is no class 1 evidence that flow regulation is superior the use of a differential pressure valve in treating hydrocephalus in children or adults (Hanlo et al., 2003; Ziebell et al., 2013).

Differential pressure valves

This type of valve utilizes a very simple concept—opening and closing pressures. When the differential pressure between IVP proximal to the valve and the pressure in the CSF distal to the valve is above the valve's opening pressure, the valve will open allowing CSF to flow. However, due to the valve's mechanisms, the closing pressure may be lower than the quoted opening pressure and symptoms of overdrainage may occur without siphoning. A large variety of these valves exist in the market and each one is subdivided according to their pressure range (high, medium, and low). They can be roughly placed into four groups according to their mechanism of actions: diaphragm valve, ball-in-cone valve, mitre valve, and slit valves (Table 93.3).

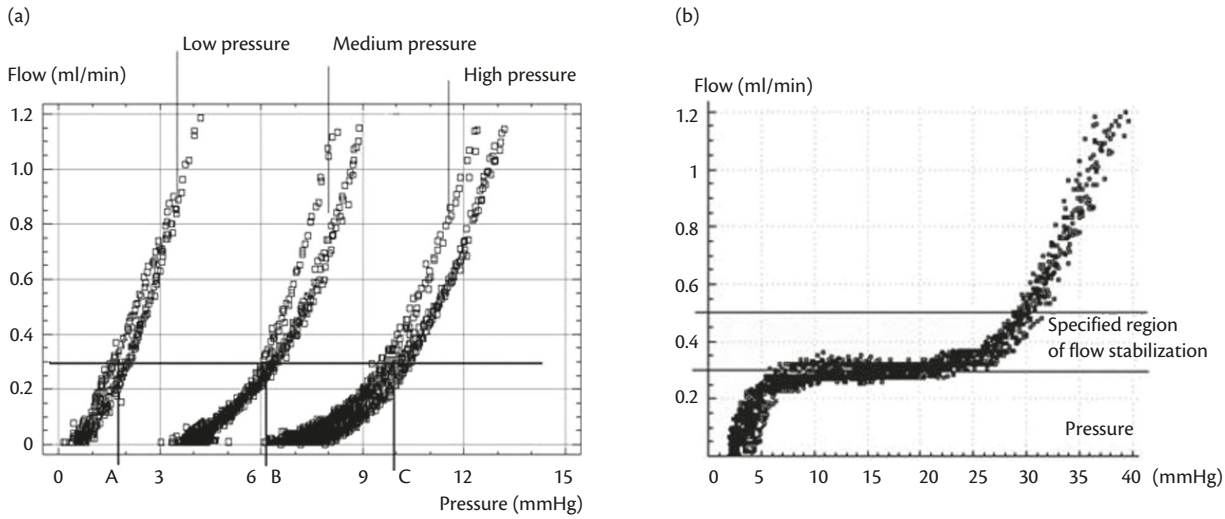

Fig. 93.1 Pressure/flow relationship in differential pressure valves at three fixed settings (A) and a flow-controlled valve (B).

(A and B) Reproduced with permission from Z. Czosnyka, M. Czosnyka, H. K. Richards et al., Laboratory Testing of Hydrocephalus Shunts—Conclusion of the U.K. Shunt Evaluation Programme, *Acta Neurochirurgica*, Volume 144, Issue 6, pp. 525–38, Copyright © 2002 Springer Nature.

Gravitational valves

This type of valve has been designed to reduce the siphoning effects of change in patient's posture by altering the opening pressure, using gravity. They are ball-in-cone differential pressure valves but with an additional gravitational unit. This is composed of a ball which would displace into the cone when the patient is upright, thus increasing resistance and reducing flow. Examples being the Integra™ H-V® valve and Mithke *Pro-Gav*® system. As with any differential pressure valve, they come in a range of different opening pressures and given this is dependent on the height of the column of fluid within the system, the choice should be based on the height of the patient. They are of particular use in lumbar shunts to reduce the common problem of postural overdrainage.

Adjustable or 'programmable' valves

These are differential pressure valves, which have a mechanism that allows adjustment of the opening pressure by the user externally. The obvious benefit is the ability to alter the opening pressure non-invasively according to the patient's symptoms and reduce the need for revision surgery in this situation. Most systems use an external magnetic field to adjust the valve—many designs exist on the market. A limitation therefore is that a strong magnetic field such as an MRI may alter the shunt opening pressure setting. It is therefore important that patients with shunts with adjustable valves know that strong magnetic fields may affect their shunt function. Equally important is that MR radiographers are aware so that shunt settings can be checked after any MRI examination (Lollis et al., 2010). Settings can usually simply be confirmed with a plain radiograph of the shunt valve, but this requires knowledge of the shunt appearance to ensure correct interpretation (Fig. 93.2).

There is no class I data to compare their efficacy to non-adjustable types of valves. Adjustable systems are, in the main, indicated in the management of idiopathic normal pressure hydrocephalus (iNPH) and have been shown to reduce postoperative overdrainage and subdural formation in these patients. They enable the stepwise reduction in valve opening pressure, and allow the titration of shunt setting against clinical response. The ability to non-invasively reduce the opening pressure over time helps to reduce the risk of developing postoperative subdural collections in patients with large non-compliant ventricles. A surgeon may also choose to use these more expensive valves in younger adults with very large ventricles or in children as a way of allowing gradual upgrading of valve pressure as the child grows taller. Whether this lowers the risk of long-term

Table 93.3 Examples of differential pressure valves and their designs

Valve design	Example	Advantage	Disadvantage
Diaphragm	• Sophysa Pulsar® • Medtronic Delta®	Simple valve. Allows ventricular CSF sampling if reservoir is proximal to valve	Silicone prone to degradation with age
Ball-in-cone	• Codman® Hakim	Less prone to ageing effects	More prone to obstruction in patients with particulate or turbid CSF
Mitre	• Integra™ Mischler Valve	Direct flow path makes obstruction less likely in patients with turbid CSF	Silicone prone to degradation with age
Slit valve	• Sophysa Phoenix® • Holter-Hausner® • Codman® Unishunt	Simple, usually cheap. Simple insertion. Small (useful in neonates). Can be placed proximally or distally	May be prone to siphoning. Do not allow shunt tapping

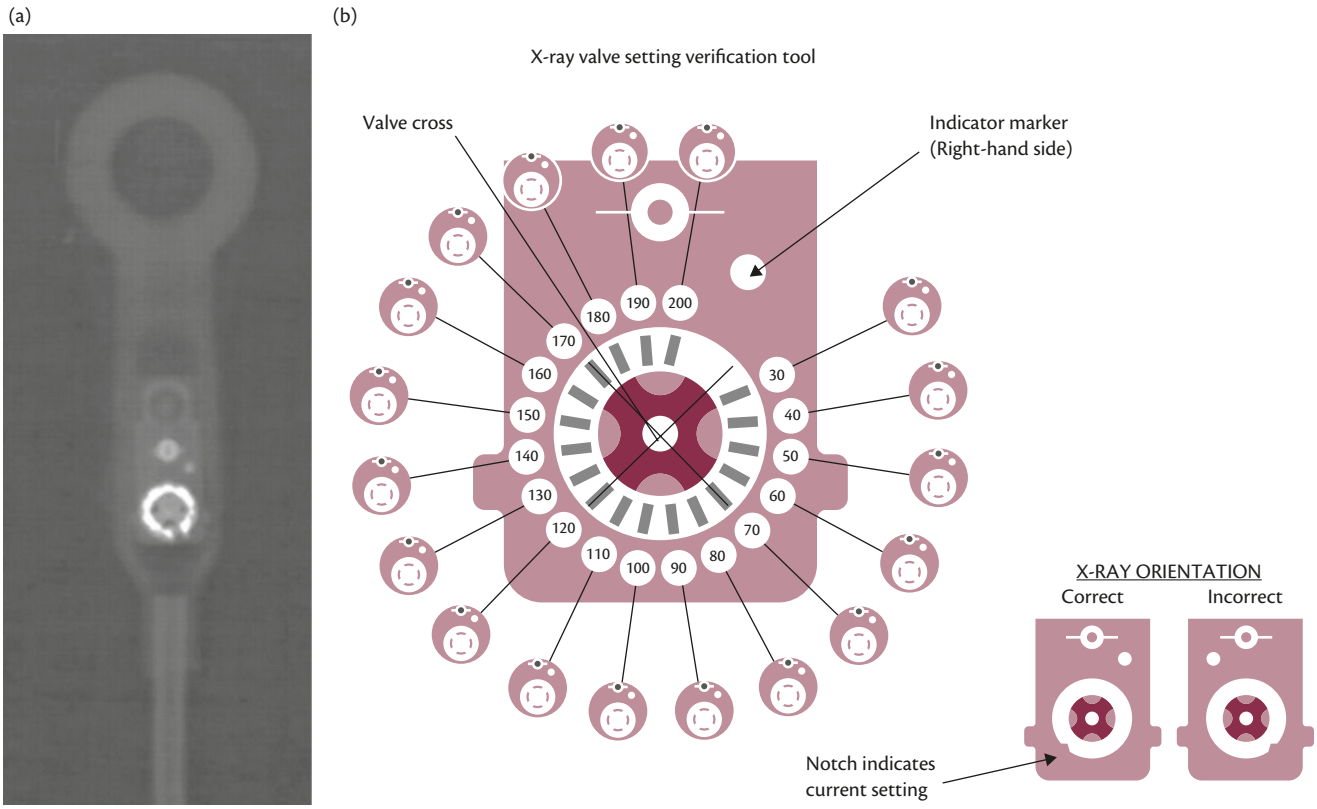

Fig. 93.2 Radiographic and diagrammatic representation of the Codman Hakim® (Depuy-Synthes) programmable differential pressure valve. Valve setting can be checked with radiograph of the valve complex and verifying the location of the notch in the valve (A) which corresponds to the valve setting (courtesy of Codman Depuy-Synthes, United Kingdom). Other valve designs use similar radiographic methods of determining valve setting.

overdrainage complications or blockage in the individual child is not yet clear from longitudinal studies.

Operative principles

External ventricular drain

Cranial CSF may be drained externally as a temporary measure through an external ventricular drain (EVD), and is often a life-saving procedure in patients with acute hydrocephalus. Temporary CSF drainage may be indicated where the CSF is contaminated with blood, when there is evidence of CSF infection, or the cause of hydrocephalus is reversible and permanent CSF diversion is not likely to be required. For the surgical technique of EVD insertion see **Box 93.1**.

Ventricular cannulation and the placement of a ventriculoperitoneal shunt

An occipitoparietal burr hole is used most commonly for the site of proximal catheter insertion, though some prefer a frontal approach, citing a reduce failure rate from choroid plexus occlusion, though this remains controversial. The use of image guidance to ensure optimum catheter position within the ventricle is become more widespread where the technology is readily available and the associated costs are reducing.

The general operative principles for shunt placement are outlined in **Box 93.2**. Whichever the preferred site of catheter entry, all efforts should be made to prevent shunt infection.

Investigation of shunt failure

In any patient with a shunt in whom shunt dysfunction is suspected, the following investigations should be performed immediately and without delay, as surgical intervention may be required urgently.

- Plain non-contrast cranial CT scan (including volume acquisition if image guidance is likely to be required for shunt revision).
- 'Shunt series' of plain radiographs to ensure shunt is in continuity. This should include radiographs that incorporate the whole shunt system: typically skull, cervical spine, chest, and abdomen in patients with a ventriculoperitoneal shunt. In patient with a known programmable valve, a dedicated radiograph perpendicular to the valve should be performed in addition to the shunt series to accurately check the valve settings.
- Laboratory tests: full blood count, coagulation, basic biochemistry as a minimum. A measure of C reactive protein is helpful if shunt infection is possible. Blood and CSF cultures should be obtained if infection is suspected.

It is vitally important old imaging is available for comparison where possible. Records should be available that describe the shunt and valve type that is implanted, though this is often made clear from the shunt series of plain radiographs. Some units are adopting a rapid MRI protocol for patients with suspected shunt failure, to limit the cranial radiation dose. This is particularly relevant in children with complex hydrocephalus that present regularly.

Box 93.1 External ventricular drain insertion technique

- Head-up position at approximately 30°. Head neutral on horse-shoe headrest (patient placed in pins if using an optical image guidance system).
- Image guidance set up and patient accurately registered to the system if being used*.
- Right-sided frontal burr hole unless contraindicated (e.g. right frontal intraventricular haematoma, asymmetric ventriculomegaly).
- Frontal hair shave and sterile preparation to allow at least 5 cm space for tunnelling of the drain.
- Drape the patient so that the tragus and ipsilateral medial canthus are visible or easily palpable.
- Place the burr hole 1–2 cm anterior to the coronal suture in the midpupillary line (Kocher's point). Plan incision so that it does not interfere with any planned surgical procedure (e.g. endoscopic ventricular surgery or pterional craniotomy for clipping anterior circulation aneurysms).
- Meticulous haemostasis—paying particular attention to bleeding bone edges (use bone wax where required), dura and pia (bipolar coagulation).
- Insert catheter perpendicular to brain surface to a depth of 5–6 cm aiming for a point that is the convergence of the ipsilateral medial canthus and tragus; this approximates the position of the foramen of Monro. If CSF does not flow at the point, then the trajectory is incorrect. Passing the catheter to a greater depth is unlikely to be successful.
- Tunnel catheter under sterile surgically prepared scalp at least 5 cm.
- Pay particular attention to securing the drain effectively without occluding it. Drains should not 'fall out' on the ward. Close and dress wound.
- Attach external drainage set under sterile conditions and set height at which CSF should be drained. Communicate this drainage height to all members of the team involved in the patients care and carefully document it in the notes.

*Image guidance (including intraoperative ultrasound) to be used at the discretion of the surgeon. It is of particular use in patients where the anatomy is abnormal (e.g. the presence of midline shift).

Shunt infection

Shunt infection is possibly the most undesirable shunt complication, and everything should be done to reduce the risk of this occurring (Di Rocco et al., 1994). The adoption of a standard departmental shunt insertion protocol addressing the multifactorial aetiology of infections has been shown to significantly reduce this risk (Kestle et al., 2011). Some shunts have been specifically designed to help prevent postoperative infection. The impregnation of catheters with antibiotics (e.g. Bactiseal®), or coating with substances that reduce bacterial adhesion (e.g. Silverline®) has been developed to reduce the rate of shunt failure from infection and have variable amounts of evidence to support their efficacy. These antimicrobial catheters do not completely eliminate the risk of infection, but provide some defence against the more common pathogens causing shunt infections, and there is currently no class 1 evidence to promote their use over cheaper systems (Klimo et al., 2014). A UK multicentre prospective randomized trial (https://www.basics.org.uk) has just completed to assess the efficacy of these different products when compared to standard shunt tubing. We await the published results with interest.

Box 93.2 Principles of ventriculoperitoneal shunt insertion: Complication avoidance

- **Preoperative considerations.** Consider chlorhexidine scalp wash the day before surgery. Ensure preoperative antibiotics are given prior to the first incision as per the hospital's antibiotic guidelines.
- **Theatre etiquette.** The number of staff present in the operating theatre should be kept to a safe minimum and traffic of personnel should be discouraged. Doors should be kept closed at all time. All staff should wear surgical masks. Laminar flow operating theatres should be used where available.
- **Patient positioning.** Ensure the anaesthetist positions the endotracheal tube away from the side of the planned surgery. Ensure that the head is positioned to allow full access to the chosen position of proximal catheter insertion. The head position should allow unhindered access to the neck and clavicle to make distal catheter tunnelling as easy and safe as possible.
- **Preparation of surgical site.** Mark planned incisions with indelible marker. Shave hair at proximal catheter insertion point and along tunnelling path. Meticulous preparation, allowing time for surgical prep to evaporate. Sterile local anaesthetic with adrenalin injected into the skin at both primal and distal incision sites. Ensure all drapes are carefully placed to maintain sterility at all times.
- **Surgical technique.** Double glove. Careful handling of tissues at all time. Make particular care not to handle wound edges. Cover all wound edges with antiseptic soaked gauze or drapes.
- **Shunt tunnelling and preparation of a pocket for the valve.** Make all efforts to ensure tunnelling tool passes over the clavicle. Some surgeons prefer to tunnel from the distal incision to make this easier. Ensure a subcutaneous pocket is fashioned that is large enough to accommodate the valve of choice without kinking the shunt tubing.
- **Handling of shunt components**. Use new gloves when handling the shunt for the first time. Always use non-toothed instruments to manipulate the shunt components. Preassemble shunt components away from the patient with new sterile gloves if possible. Open shunt components at the last minute, and keep covered and submerged in saline once opened and primed.
- **Haemostasis and wound closure.** Meticulous attention to detail to ensure haemostasis and proper wound edge apposition when closing the wound. This is of particular importance in infants.
- **Adherence to a departmental protocol.** The use of a departmental protocol for shunt insertion has been shown to drive down infection rates; irrespective of what it contains. Some may include the use of routine intrathecal antibiotics, using specific skin preparation or drapes, or using antibiotic-impregnated shunts.

Endoscopic surgery for the treatment of hydrocephalus

Over the past 20 years there has been a huge resurgence of interest in the use of endoscopic techniques to treat hydrocephalus, such as third ventriculostomy (ETV). During this period, advances in endoscope design, improved optics, and image display (including high definition and more recently 3D) has enabled these procedures to be undertaken with a greater degree of accuracy and safety. The attraction of giving children and adults the chance of escaping the numerous inherent complications of CSF shunts has led to the rapid expansion of neurosurgeons offering a neuroendoscopic alternative as a first-line treatment of hydrocephalus.

Box 93.3 Clinical indications for endoscopic third ventriculostomy

Strong indications

- Delayed-onset aqueduct stenosis
- CSF shunt obstruction in any patient with a history of obstructive hydrocephalus and large enough ventricles for endoscopy to be safe
- Older patients with spina bifida and a blocked shunt
- Obstructive hydrocephalus caused by pineal region or posterior fossa tumours; either as a primary treatment or prior to more definitive tumour resection. May be combined with endoscopic biopsy

Weaker indications

- Neonates with aqueduct stenosis or spina bifida
- CSF shunt obstruction in children or adults with a history of communicating hydrocephalus

Box 93.4 Endoscopic third ventriculostomy technique: Basic principles

- **Head-up position:** The table is tilted and the patient's neck is flexed to produce a head-up tilt of approximately 30°. This helps to prevent excessive CSF loss, which may cause pneumocephalus, subdural hematomas, and upward herniation of cerebellar tumours.
- **Siting the burr hole correctly:** It should be placed just anterior (or on) the coronal suture in the midpupillary line, which is approximately 3 cm from the midline in an adult and approximately 2 cm from the midline in a small child.
- **Using the correct trajectory and landmarks to cannulate the ventricle:** If the external auditory meatus and ipsilateral medial canthus are used for the trajectory, the tip of the cannula should lie at the foramen of Monro provided that the depth is appropriate (approximately 6 cm in an adult and approximately 4 cm in a child).
- **Perforating the floor of the third ventricle anterior to the mammillary bodies in the midline and usually at its thinnest part:** This is often halfway between the mammillary bodies and the infundibulum. The instrument used to perforate the floor should preferably be blunt-tipped but depends on the individual surgeon's preference ranging from the scope tip itself to thin unipolar wire electrodes, balloon catheters, or laser.
- **Clear visualization of the subarachnoid space after making the hole:** The basilar artery, brainstem, and clivus should be clearly seen through the stoma, which is usually enlarged with a balloon catheter. Pulsations ('flapping') of the floor of the third ventricle at the end of the procedure tend to indicate a favourable long-term outcome. Any residual Lilliquist membranes in the prepontine space should be divided if safe to do so.
- **Use of image guidance:** When the ventricular anatomy seems complex or difficult to interpret on standard scans, neuronavigation systems should be used.

Endoscopic third ventriculostomy

History

The first successful endoscopic third ventriculostomy was performed by Mixter in 1923 on a 9-month-old child with non-communicating hydrocephalus, using a small urethroscope (Mixter, 1923). Scarff advocated ETV as a rational method of treating obstructive hydrocephalus as far back as 1935 (Scarff, 1936), but reports in the literature largely comprised single cases or small series until the 1980s and 1990s, when the operation gained more widespread popularity. The indications for ETV are described in Box 93.3.

Anatomy

The standard technique for performing an ETV is described in Box 93.4, though there are various technical nuances and variations. After successful cannulation of the frontal horn of the lateral ventricle (usually the right), the foramen of Monro can be identified by following the thalamostriate or septal veins. They typically meet at the foramen, which also has choroid plexus running anteriorly in the choroidal fissure up to or through it (Fig. 93.3). After carefully passing the endoscope through the foramen (paying particular care not to damage or stretch the fornix) the typical features of the third ventricular floor can be identified. Posteriorly one should visualize the mammillary bodies, anteriorly the infundibular recess and the lamina terminalis (Fig. 93.3). In cases where the ventricular floor is very stretched and thinned, one may be able to see the basilar artery in the prepontine cistern through a thinned membrane.

Preoperative investigations

CT is often sufficient to make the diagnosis of obstructive hydrocephalus, but this should be augmented with the detail available with magnetic resonance imaging in all cases. MR imaging of the brain with midline sagittal views is useful to demonstrate the presence or absence of flow voids in the third ventricle or aqueduct. Cine-MRI may help to illustrate these flow voids. MRI is also essential to clarify the relative size of the lateral, third, and fourth ventricles, and to show the anatomy of the basilar artery and prepontine space. This will establish whether the entry of an instrument into the prepontine space is technically feasible. Volume acquisition scans should be obtained if intraoperative image guidance is going to be used. Where available, a high-resolution T2 MR scan in the midsagittal plane should be obtained, such as provided by constructive interference in steady state (CISS) sequences or equivalent. These not only give better anatomical detail but will also detect if there are any other obstructive membranes within the ventricle that may also be amenable to endoscopic treatment (Fig. 93.4).

A radiologic diagnosis of aqueduct stenosis is usually made on the basis of the sagittal MRI image but the radiologic differentiation between obstructive and communicating hydrocephalus is sometimes uncertain. CSF infusion studies through a ventricular catheter or spinal needle can be used to assess the relative compliance of the intraventricular and extracranial CSF compartments, thus giving an indirect assessment of the degree of obstruction to outward flow from the ventricles. This test has been used to select suitable candidates for third ventriculostomy, as well as shunting, though is not routine (Boon et al., 1997; Bech-Azeddine et al., 2007).

Contraindications

Clearly if the anatomy of the prepontine space has been severely distorted, for example, by a tumour, severe meningitis, or vascular abnormality, third ventriculostomy should probably not be attempted. With such a poor chance of success in premature neonates with posthaemorrhagic hydrocephalus, it is questionable whether the technique should be used routinely in these babies.

Technique

There is great variability between individual surgeons in the details of their technique, but there are certain basic principles that are vital for the success of the procedure (Box 93.4).

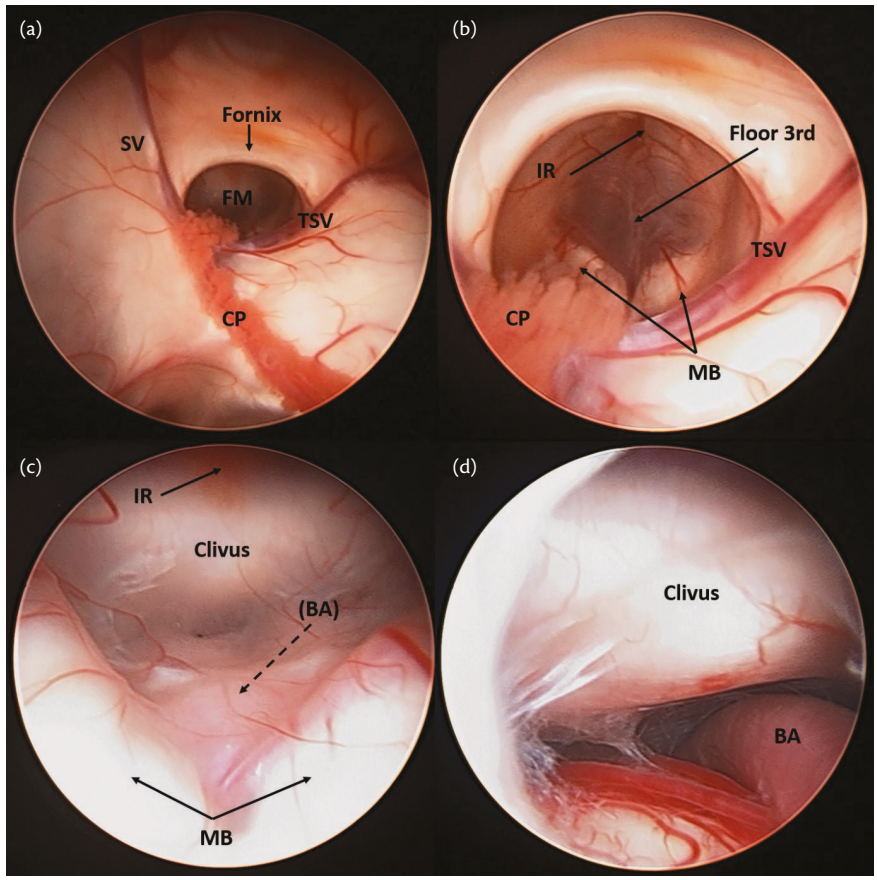

Fig. 93.3 Intraoperative neuroendoscopic images during ETV for aqueduct stenosis. SV, septal vein; TSV, thalamostriate vein; CP, choroid plexus; IR, infundibular recess; MB, mammillary bodies; BA, basilar artery; FM, foramen of Monro.
A) Foramen of Monro from a standard right frontal approach to the lateral ventricle.
B) View of the third ventricular floor through the foramen of Monro.
C) Floor of the third ventricle. In this case very thinned due to the chronic hydrocephalus. The basilar artery can be seen through the translucent floor.
D) View of the basilar artery in the prepontine cistern after third ventriculostomy. The scope is passed through the stoma to ensure there is no obstruction to CSF flow from Lilliquist membrane.

Artificial CSF should be used whenever possible for irrigation of the ventricles during ventriculoscopy because of the apparently detrimental effect of saline washouts on the brain and ependyma. Some surgeons use a temporary EVD at the end of the procedure, whereas others do not use any CSF drainage devices. The authors routinely place a subcutaneous ventricular access reservoir and have found it extremely useful in the follow-up of patients. As well as allowing immediate access to the CSF space in the case of acute life-threatening hydrocephalus due to stoma blockage, a ventricular access device also can be used to non-surgically to monitor ICP. Postoperative

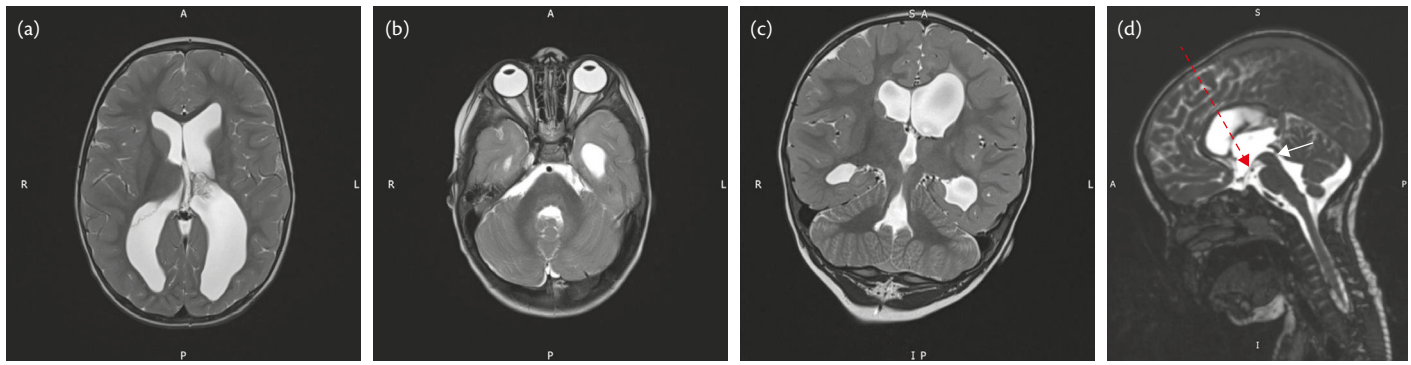

Fig. 93.4 A 2-year-old boy with asymmetric tri-ventricular hydrocephalus as shown in the axial and coronal T2-weighted MR images (A–C). Sagittal CISS MR imaging illustrated aqueduct obstruction from a web (D, white arrow). Dotted red arrow illustrates the required trajectory of the endoscope for third ventriculostomy.

analysis of CSF dynamics with the use of a constant rate infusion study can be used to predict stoma function in these patients, and can be a useful tool in patients after ETV where there is clinical doubt as to the success of the procedure (Aquilina et al., 2012).

Outcome after ETV

The possibility of achieving shunt independence in both children and adults with hydrocephalus is a tempting proposition. Indeed, in certain individuals ETV is more effective in the long term than shunting and does not carry the inevitable long-term complications associated with implanted shunt hardware. The publication of an ETV success score gives an idea of the relative probability of achieving shunt independence (Kulkarni et al., 2010b). This provides a clinician with a numerical score for a patient calculated as a function of their age, the aetiology of the hydrocephalus and whether or not they have previously treated with a shunt. The total score is approximate percentage predicted probability of a successful ETV, defined as long-term shunt freedom. Poor scores are obtained in patients less than 1 month, those with postinfectious hydrocephalus, and those that have previously been shunted. The chance of ETV success is greater in children over 10 years of age with hydrocephalus caused by obstruction at the level of the cerebral aqueduct who have not been previously treated with a shunt.

A continuation of this work has shown that ETV is less effective than shunting in the short term (less than 3 months), but more effective in the long term, that is, if the ETV is successful after 3 months postoperatively, then the risk of failure long term is better than if a shunt was used instead (Kulkarni et al., 2010a). This observation has yet to be tested in a prospective randomized trial and carries the usual inherent limitations of a retrospective study. It does however reflect the commonly held view that ETV is much more successful in older children or adults with obstructive hydrocephalus with aqueduct stenosis, than in neonates with postmeningitis or haemorrhagic hydrocephalus.

Other forms of endoscopic CSF diversion procedures

Septostomy

By Communicating both lateral ventricles with an endoscopic septostomy, CSF can bypass blockage that causes asymmetrical univentricular hydrocephalus. Hydrocephalus can then be controlled through a unilateral lateral ventricular shunt or an ETV. In the case of an isolated trapped lateral ventricle, it may be all that is required.

Multiloculated hydrocephalus

Complex multiloculated hydrocephalus is a common consequence of neonatal intraventricular haemorrhage and intracranial sepsis. Management may be through the use of multiple shunts, or shunt catheters, which creates a complex shunt system and is the nightmare case for the on call neurosurgical team when a patient presents with shunt dysfunction (**figure 93.5**). In these cases, a flexible endoscope is of particular use as it allows the surgeon to divide multiple intraventricular adhesions through as few burr holes as possible. By communicating these loculations, CSF drainage can be managed through a single shunt or ETV, providing a much more satisfactory surgical outcome.

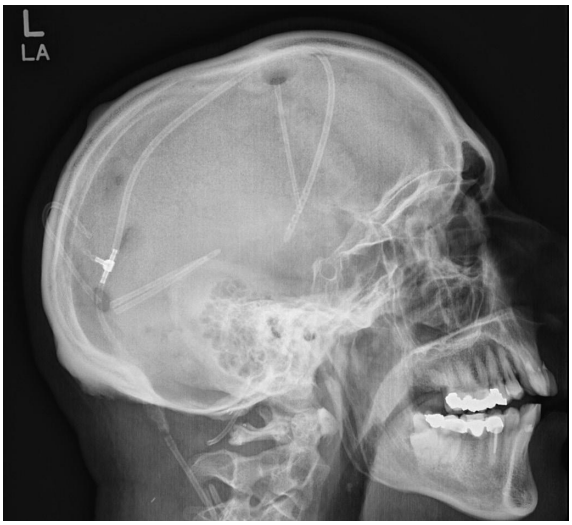

Fig. 93.5 Multiple proximal shunt catheters seen on a plain anteroposterior (AP) radiograph. The nightmare hydrocephalus case.

Aqueductoplasty

Endoscopic aqueductoplasty and aqueductal stenting as treatments for hydrocephalus caused by aqueduct stenosis are controversial techniques that are not widely practised. This is primarily because of the high risk of neurologic complications as a result of damage to midbrain structures causing disconjugate eye movements, (Parinaud's syndrome) and oculomotor or trochlear nerve palsies. Furthermore, the shape of the aqueduct, which most often depicts an S-shape in the midsagittal plane, increases the risk of midbrain trauma if rigid endoscopes or catheters are used. However, the technique does directly restore the physiologic CSF pathway and as endoscope technology evolves, is becoming increasingly possible in experienced hands to achieve without complications. In particular, endoscopic stenting of the aqueduct may have a role in the treatment of patients with an isolated obstructed fourth ventricle after shunting.

Endoscopic choroid plexus coagulation

Before the introduction of ventricular shunting procedures in the 1950s, open extirpation of the choroid plexus, first described by Dandy in 1918, was the most commonly performed operation for infantile hydrocephalus. The procedure had a high mortality rate and was largely abandoned after the introduction of shunting procedures. The introduction of endoscopic techniques to coagulate the choroid plexus led to a significant improvement in operative results, but has not established itself as a standard technique (Pople and Ettles, 1995). There is growing evidence that in combination with ETV it may be of more benefit as first-line treatment (Stone and Warf, 2014). Patients who require shunt insertion because of failure of choroid plexus coagulation to control hydrocephalus undergo fewer subsequent shunt revisions. This is probably the result of reduced rates of proximal catheter blockage by choroid plexus ingrowth. The indications for this procedure are described in **Box 93.5**.

Box 93.5 Indications for endoscopic choroid plexus coagulation

Infants with slowly progressive communicating hydrocephalus: Success rates in this group of patients as measured by shunt independence of up to 64% at 10 years of follow-up have been achieved

Hydrocephalus as a result of CSF overproduction: Choroid plexus papilloma and hyperplasia are conditions in which overproduction of CSF may result in hydrocephalus. Endoscopic choroid plexus coagulation deals directly with the pathologic cause of the hydrocephalus and may obviate the need for ventricular shunting.

Communicating hydrocephalus where shunt insertion is not feasible, such as in infants where there is persistent posthaemorrhagic hydrocephalus associated with necrotizing enterocolitis.

Intractable shunt failure: In addition to ensuring a shunt functions acutely, these patients may benefit by a reduction in proximal shunt occlusion rates

Endoscopic choroid plexus coagulation is contraindicated in obstructive hydrocephalus and in patients with rapidly progressive communicating hydrocephalus with acutely raised ICP

Endoscopic treatment of developmental posterior fossa cysts

The rapid development of intraventricular neuroendoscopy has revolutionized the treatment of hydrocephalus caused by developmental posterior fossa cystic abnormalities, such as Dandy Walker Syndrome and Blake's pouch cysts, either through aqueductoplasty, or via endoscopically fenestrating cysts to allow communication and drainage through an ETV or shunt.

Endoscopic removal/aspiration of obstructive intraventricular cysts

Arachnoid cysts

Endoscopic decompression and fenestration are most useful in intraventricular arachnoid cysts, midline septal cysts, and arachnoid cysts of the suprasellar region. The recomended treatment for middle fossa arachnoid cysts remains controversial, and fenestration, either endoscopically or by open technique, seems to have a fairly high long-term failure rate (30–50%): often a conservative approach is best. Cysts of the quadrigeminal cistern can be treated by third ventriculoscopy and fenestration of the cyst into the third ventricle, often alongside an ETV.

Colloid cyst of the third ventricle

Endoscopic removal or aspiration and coagulation of colloid cysts which are causing obstructive hydrocephalus has been used in the authors' unit since the early 1980s. The benefits of a less invasive approach to these cysts seem to outweigh the disadvantage of more frequent incomplete removal. This remains controversial, with some surgeons still advocating an open transcortical or interhemispheric transcollosal approach. However, endoscopic colloid cyst surgery is now recognized as potentially superior alternative to open surgery when in experienced hands. A successful result in terms of control of hydrocephalus, symptomatic improvement, and removal of most of the cyst has been achieved in most cases in various reported series. A second burr hole to allow passage of a reasonably large-bore suction catheter down a separate tract for aspiration of the sometimes thick viscous cyst contents may be required. When the hydrocephalus is not severe, endoscopy can be combined with stereotactic guidance into the ventricle. Indeed, Image guidance is very useful in all cases to plan the optimum scope trajectory to remove a colloid cyst as it is often different to that used in a standard ETV.

Summary

Hydrocephalus surgery is a complex clinical science. There is little clinical evidence to say whether any one of the vast range of complex shunt devices on the market are superior to another. The development of endoscopic technology and neuroimaging techniques has made the prospect of hydrocephalic patients to be managed without implanted shunt hardware a real possibility. The modern neurosurgeon needs to be aware of all the options available to make the best decisions for their patients on an individual basis.

Normal pressure hydrocephalus

Nicole C. Keong

Introduction

The concept of a 'symptomatic occult hydrocephalus with 'normal' CSF (cerebrospinal fluid) pressure' was described by Hakim and Adams in 1965 in their landmark paper of observations based on three cases, two post-traumatic and one idiopathic, and subsequently expanded with the support of others (Adams et al., 1965; Hakim and Adams, 1965). The term was in fact coined by Hakim for his thesis the year prior to the publication of that paper. Current guidelines and research are focused primarily on the idiopathic normal pressure hydrocephalus (iNPH) as opposed to secondary normal pressure hydrocephalus (secondary NPH), occurring following subarachnoid haemorrhage, head injury, intracranial surgery, or meningitis.

The term 'normal pressure' hydrocephalus is misleading as continuous CSF pressure measurements indicate that intracranial pressure is on average slightly higher than normal and there are waves of increased intracranial pressure, particularly during rapid eye movement (REM) sleep. Such nomenclature is also thought by some to promote an underestimation of the condition, implying a type of hydrocephalus requiring less urgent access to diagnosis and treatment. As a result, some experts prefer the term idiopathic adult hydrocephalus syndrome or chronic communicating hydrocephalus.

Pathophysiology

Theories of pathogenesis and research evidence

Many theories have been advanced to explain the underlying mechanisms by which the NPH syndrome develops. However, the basic pathophysiological processes still remain unclear. The major theory streams proposed for the pathogenesis of NPH can be loosely organized into (i) structural, (ii) cerebral blood flow, and (iii) CSF flow subgroups. The components of each theory stream are expanded in the text that follows here, although the list of studies supporting each section should be considered by no means exhaustive (see (Momjian et al., 2004; Keong et al., 2016) for detailed reviews; **Table 94.1** for an overall illustration and additional references).

Structural

Tissue distortion

Hakim and other authors have hypothesized that the starting point in the pathophysiology of NPH is tissue distortion secondary to raised intraventricular pressure (Hakim et al., 1976). Compression or stretching of both parenchyma and blood vessels produce loss of elasticity, atrophy, and/or ischaemic injury. This produces a state of normal CSF pressures that result in a reversal of the gradient of pressure and stress upon the cerebral mantle.

Interstitial fluid pressure increase

Loss of elasticity in the parenchyma results in a pressure gradient between the ventricles and periventricular tissues and/or between convexity subarachnoid spaces and the parenchyma. Fluid stagnation disrupts the balance of hydrostatic vs. osmotic pressures, resulting in reversal of interstitial fluid flow, subsequent oedema, and failure of drainage of vasoactive metabolites. Local cerebrovascular reactivity is reduced (Marmarou et al., 1980). Damage to cell and blood vessel walls causes further leakage of fluid into the interstitial space.

Biomechanical

The presence of B waves may result in intermittent raised intracranial pressures, particularly during REM sleep. This and the change in properties of ageing brain parenchyma may make the older age group susceptible to progressive ventricular enlargement (Factora, 2006). Modelling of brain deformation in chronic communicating hydrocephalus suggests that a combination of reversal of interstitial fluid flow into the parenchyma and reduced tissue elasticity occurs (Pena et al., 2002). The resultant profile of raised fluid pressure follows a U-shaped curve from the ventricular surface to the brain convexity (i.e. the minimum occurring at the middle of the cerebral mantle). This differential, also confirmed on cerebral blood flow (CBF) profiles plotted as a function of distance from the ventricles, may explain how the process of progressive ventriculomegaly affects the white matter arranged between the ventricles and cortex to varying degrees of severity (Momjian et al., 2004). This suggests that a common biomechanical process exists, causing the concurrent degradation of structural integrity within white matter, interstitial space, and cerebral vasculature.

Table 94.1 Theories of NPH pathogenesis. Images Courtesy of Dr Nicole Keong ©

	Structural	Cerebral Blood Flow	CSF Flow
			Key Concepts	• Tissue distortion • Loss of elasticity • Reversal of interstitial fluid flow = oedema • Failure of drainage of vasoactive metabolites • Brain deformation • U-shaped curve	• Ventricular expansion distorts connections and/or blood vessels between basal ganglia and frontal cortex • Deep lacunar infarctions • Loss of elasticity in parenchyma	• Adult communicating hydrocephalus • Imbalance between CSF production and reabsorption • Reduced CSF production • Resistance to CSF outflow increased • Inability to clear toxic metabolic products
Key theory streams	• *Tissue distortion* • *Interstitial fluid pressure increase* • *Biomechanical*	• *Watershed ischaemia* • *Vascular disease*	• *CSF flow disturbance* • *CSF hydrodynamics* • *Failure of drainage of vasoactive metabolites*

Cerebral blood flow

Watershed ischaemia

Positron emission tomography (PET), xenon-enhanced computed tomography (xenon-computed tomographic (CT), and single-photon emission computed tomography (SPECT) studies all indicate widespread cortical and subcortical hypometabolism and impaired global CBF (Tedeschi et al., 1995). This may result in dysfunctional regional cerebral autoregulation and watershed ischaemia occurring in the corona radiata. However, there has been a frustrating lack of congruence within the group of studies examining CBF in NPH. Only a few studies have attempted to combine CBF measurement with structural imaging coregistration to achieve a good anatomical basis for comparisons of CBF data (Owler et al., 2004).

Vascular disease

Deep white matter hyperintensities (DWMH) found on imaging in some patients with NPH have also provoked debate about cerebral small vessel disease and vascular encephalopathy. Ventricular expansion may distort the connections and/or blood vessels between the basal ganglia and frontal cortex, producing deep lacunar infarctions, or lead to loss of elasticity in the parenchyma. Ischaemia in the white matter tracts involved in frontal executive function, gait, and micturition may be implicated as a trigger for the pathogenesis of NPH. DWMH have been shown to both negatively correlate with degree of improvement (Krauss et al., 1996) and have no correlation to poor postoperative outcome (Tullberg et al., 2001). The presence of such lesions may therefore not preclude good outcome following intervention.

CSF flow

CSF flow disorder

Adult communicating hydrocephalus is thought to be a form of CSF circulation disorder, involving an imbalance between CSF production and reabsorption (Box 94.1, expanded from the original reference) (Pickard, 1982). The resulting excess accumulation of cerebrospinal fluid is thought to result in ventriculomegaly. Abnormalities of the ageing brain (loss of elasticity of the neuropil, extracellular matrix, and parenchyma) also contribute. B wave pressures behave in a 'water hammer' fashion, exerting intermittently high pressures on the parenchyma. Therefore, in addition to disturbances within the CSF circulation, an imbalance exists between the forces driving progressive ventriculomegaly and the architectural forces within the brain parenchyma that should naturally oppose this.

CSF hydrodynamics

There is physiological evidence to suggest that this imbalance exists. Czosnyka et al. examined the question of age dependence of cerebrospinal fluid pressure-volume compensation by performing CSF infusion studies on a group of patients with symptomatic hydrocephalus and normal intracranial pressures (ICP) (Czosnyka et al., 2001). They demonstrated that resistance to CSF outflow (defined as Rout or Rcsf) increased in a nonlinear fashion with advancing age and was associated with a decrease in the CSF production rate, which also occurred with increasing age. Both the pulse amplitude of the ICP waveform and the slope of the amplitude-ICP regression line increased significantly with advancing age. There was a nonlinear increase in the elastance coefficient with age and was thought to represent progressive brain parenchymal stiffness. Some have proposed a 'two-hit' hypothesis, in which adults who had 'benign external hydrocephalus' in their infancy suffer a second hit with deep white matter ischaemia due to vascular disease in late adulthood, thus starting the chain of events leading to the iNPH syndrome (Bradley et al., 2006).

Box 94.1 Disturbance of CSF regulation

Defects of flow in the subarachnoid space and CSF circulation:

Leptomeningeal inflammation
Infections
Haemorrhage
Meningitis
Carcinomatosis
Foreign matter
Tonsillar elongation/prolapse or basilar impression
Masses (neoplastic and non-neoplastic)
Subarachnoid blocks (such as those due to the above, as well as other arachnoidal or aqueductal webbing, membranes, and non-confluent CSF compartments)

Defects of absorption of CSF at the arachnoid granulations

Congenital deficiency (i.e. absence of arachnoid granulations)
Raised cerebral venous sinus pressure

Abnormalities of the CSF

Excessive production of CSF or abnormally high CSF volumes
Raised intraventricular CSF pulse pressure—for example, in the presence of a choroid plexus papilloma.
Increased CSF viscosity secondary to high protein content—for example, in the presence of spinal neurofibromas such as described in Froin's syndrome (in which CSF demonstrates a combination of elevated protein content, xanthochromia, and hypercoagulability)

Data from Pickard, J. D., Adult communicating hydrocephalus, *British Journal of Hospital Medicine*, pp. 27–40, Copyright © 1982.

Failure of drainage of vasoactive metabolites

Abnormalities in CSF production and turnover may also lead to inefficient or failed clearance of toxic molecules. An inability to clear potentially toxic metabolic products, such as amyloid ß-peptides (Aß) and tau protein, could lead to an increase in their concentration in brain interstitial fluid, creating a potentially hostile *milieu* for neuronal function and survival. The two changes noted in ageing, reduced CSF production, and increased resistance to CSF outflow, may be implicated in the pathophysiology of Alzheimer's disease and NPH. A predominance of reduced CSF production and turnover may manifest as Alzheimer's disease. Conversely, NPH may result from a predominant increase in resistance to CSF outflow. However, a prospective, randomized, double-blinded, placebo-controlled trial evaluating the safety and effectiveness of a surgically implanted shunt in subjects with probable Alzheimer's disease involving 215 subjects (Silverberg et al., 2008) did not demonstrate any benefit in low-flow CSF shunting in subjects with mild to severe Alzheimer's disease. Indeed, it may be that a sufficient level of CSF circulatory disorder is required to benefit from shunting although the threshold of Rout that is associated with improvement from shunting still continues

to provoke debate. A disease spectrum may exist, including a subset who either have both conditions or have risks of developing both even if one process is predominant.

Preoperative

Clinical presentation of classic NPH

NPH is subject to both over- and underdiagnosis because the clinical features supporting the diagnosis of NPH are commonly encountered in older age or patients with other neurodegenerative conditions (Relkin et al., 2005). This poses a diagnostic challenge as many patients with potentially curable NPH are often misdiagnosed as having Alzheimer's disease or vascular dementia and *vice versa*. As a consequence, the precise incidence and prevalence of NPH remains controversial, estimates range from as rare as 1.3 per million to as frequent as 4 per 1000 depending on the diagnostic criteria used and the sample population. The classic triad described in relation to NPH is that of a gait disturbance, dementia, and urinary incontinence. Patients frequently present with an incomplete triad, particularly if the duration of symptom onset to diagnosis is relatively short.

Gait disorder

The typical pattern is that of unsteadiness, a predisposition to falls, and a broad-based stance. Gait stride is reduced and patients may shuffle or walk as if their feet are stuck to the floor (i.e. a 'magnetic' gait). Fisher further provided the classic term of hydrocephalic ataxia-abasia to describe the overall forward leaning posture, wider sway, and imbalance that may be accentuated by eye closure (Fisher, 1977). Common observations include decreased length, height, and speed as well as *en bloc* turning. The gait disturbance may share common features with other types of frontotemporal pathologies. There are similarities with Parkinson's disease. This can be a difficult differential diagnosis if the more classic hallmarks of that degenerative condition are not obvious, such as tremor, rigidity and mask-like facies (Keong et al., 2011). There should be an absence of focal deficits, hypertonia, and hyperreflexia, which favour other neurodegenerative conditions. Standardized measures of gait examination have also been attempted (see Table 94.2).

Cognitive disturbance

Deficits are traditionally assessed at the bedside using a mini-mental state examination (MMSE). The absence of focal cortical deficits, such as agnosia or aphasia, should be confirmed. However, such approaches have significant limitations. Doubts have been raised about the reproducibility of test scores by multiple operators. Neuropsychological testing is essential to distinguish the pattern of dementia in NPH from other conditions such as age-related cognitive decline from atrophy and Alzheimer's disease (see Table 94.2). Formal neuropsychology, using a battery of focused tests, such as in the Dutch study (Boon et al., 1998), is used by relatively few groups. Yet, specific patterns of cognitive impairment, in the form of a

Table 94.2 Measures used for assessment in NPH

Assessment	(References)	Scale	Description
Gait	(Boon et al., 1997)	2–40	10 features of gait into walking score (0–20), number of steps and number of seconds for a 10-metre walk (0–20)
	(Hellström et al., 2012b)	0–100	Gait domain evaluated from means of measurements of the number of steps and seconds needed to walk 10 metres at a free pace, and an ordinal rating of the gait. This results in two sets of continuous data (11 gait categories) and two sets of ordinal data (8 rating categories).
	(Tinetti, 1986)	16 balance	
	(Podsiadlo and Richardson, 1991)	12 gait Timed in secs	Performance test of balance and gait of manoeuvres used during daily activities. Balance portion consist of nine manoeuvres graded on an ordinal scale as normal, adaptive, or abnormal. Gait portion rates seven gait characteristics as normal or abnormal. Timed 'up and go' (TU&GT)—functional mobility tested in frail elderly. Time required to rise to standing from a standard armchair, walk 3 metres, turn, walk back to the armchair and sit down.
Cognition	(Boon et al., 1997)	Test battery	Dementia scale composed of the 10-word test, digit span forward and backward, trail making, and finger tapping
	(Iddon et al., 1999)	Test battery	MMSE, Kendrick object learning test (KOLT), selected CANTAB battery (verbal fluency, memory, and attention)
	(Kubo et al., 2008)	Test battery	MMSE, frontal assessment battery, trail making test part A
	(Hellström et al., 2012a)	Combination	Grooved pegboard, the Rey Auditory Verbal Learning Task, the Swedish Stroop test
Outcome	(Stein and Langfitt, 1974)	Grade 0–IV	Grade 0 (able to work), I–II (home without or with assistance), III–IV (custodial care despite independent functioning), IV (no capacity for independent function)
	(Black, 1980)	6 grades	Excellent—Good (preillness activity without or with deficit), Fair—transient (improved), Poor—dead (poor outcome)
	(Wilson et al., 2002)	7 grades	Modified Rankin Scale (mRS) disability = 0 (no symptoms), 1–2 (no significant or slight), 3–4 (moderate to moderately severe), 5 (severe), 6 (dead)
	(Larsson et al., 1991)	Combination	Modified in use—gait = 0 (normal), 1–2 (insecure without or with cane), 3–4 (support aids), 5 (wheelchair). Living conditions = 0–1 (independent or home with assistance), 2–3 (assisted living facility), 4 (hospital)
	(Boon et al., 1997)	Combination	The Dutch NPH Scale—four clinical outcome categories but also a short neuropsychological test battery to provide a dementia scale and ten features of gait into a walking score; mRS used for assessment of disability outcome.
	(Kubo et al., 2008)	Combination	The iNPH Grading Scale—three NPH domains (cognitive impairment, gait disturbance, and urinary disturbance). Each domain is scored from 0 to 4, with higher scores indicating worse symptoms. Correlated with MMSE, Gait Status Scale (GSS), TU&GT and International Consultation on Incontinence Questionnaire—Short Form (ICIQ-SF).
	(Hellström et al., 2012b)	Combination	The European iNPH Multicentre study—comprehensive scale using assessments in four domains—gait, cognition, balance, continence. Calibrated against age-matched healthy volunteers.

subcortical frontal dysexecutive syndrome, have been demonstrated (Iddon et al., 1999). A review for the iNPH guidelines (Klinge et al., 2005) found no standardization of cognitive tests but concluded that they contributed to objective assessment of postoperative outcome.

Urinary incontinence

This is the third component of classic NPH. Such episodic or persistent urinary disturbance should not be attributable to primary urological disorders. Less commonly, both urinary and faecal incontinence are present. In the context of lower order symptoms, such as urgency, frequency, or nocturia, iNPH guidelines require that two out of three of these should be present (Relkin et al., 2005). Urodynamic studies may be helpful in distinguishing NPH urinary dysfunction vs. common comorbidities (prostatism in men, recurrent urinary tract symptoms in women or bladder dystonia/dysautonomia), as well as other conditions in the spectrum of 'neurogenic bladder syndrome'.

Complex NPH presentations

Comorbidities

The syndrome of NPH does exhibit characteristics that overlap with other neurodegenerative conditions. An early preclinical trigger is hypothesized to lead to either Alzheimer's disease or NPH (Silverberg et al., 2003) and may explain the presence of cerebral amyloid deposition in both conditions. NPH is one of the differential diagnoses in atypical Parkinson's disease and within the 'vascular parkinsonism' spectrum that also includes other types of higher-level gait disorders with cognitive disturbance. Unusual but well-recognized cognitive manifestations of NPH, including behavioural changes, low mood, paranoia, and hallucinations, may be difficult to distinguish from psychiatric conditions such as depression and schizophrenia. Urinary dysfunction may also be dependent on gait and/or cognitive status. Predominance of early urinary incontinence with delayed onset of the latter may well favour other neurological diagnoses. In patients with significant comorbidities coexisting, such as cardiac disease and vascular risk burden, the challenge, therefore, is to provide the highest level of testing possible to characterize the 'NPH' component remediable to CSF shunting, in order to facilitate a considered approach towards weighing the relative risks vs. benefits of surgical intervention.

Variations

Lethargy, loss of interest, drowsiness and visuo-spatial disturbances have been reported but the presence of these symptoms without the supporting clinical triad should indicate a need for further investigations. Other forms of hydrocephalus may also present with the NPH syndrome. Longstanding overt ventriculomegaly in adults (LOVA) is a form of hydrocephalus which develops during childhood but presents relatively late in adulthood. Patients may present anywhere in the spectrum of hydrocephalic symptoms, from subacute symptoms and signs of raised intracranial pressure to the more insidious triad of NPH, comprising gait disturbance, cognitive decline, and/or urinary incontinence (Keong et al., 2011). In this condition, adults classically present with severe ventriculomegaly involving the lateral and third ventricles, as well as obliterated cortical sulci, found on imaging. Patients may exhibit longstanding macrocephalus measuring more than two standard deviations above mean in head circumference and/or neuroradiological evidence of a significantly expanded or destroyed sella turcica. LOVA is treatable with shunting (but requires careful control with pressure-programmable valves) and endoscopic third ventriculostomy is mostly effective (Oi et al., 2000). In other hydrocephalus subgroups presenting with the NPH syndrome, aqueduct stenosis may feature but is frequently incomplete. There may be evidence of intrinsic semi-obstruction, such as webbing within the aqueduct, or external compression, for example, distortion from middle cranial fossa arachnoid cysts. As the stenosis of the aqueduct may therefore be secondary, third ventriculostomy is a possible option but ventriculoperitoneal shunting may be more effective in some cases. Detailed imaging of CSF compartments (such as additional three-dimensional T2-weighted and CISS magnetic resonance sequences) may be useful in evaluating for the presence or absence of CSF-intensity lesions to best inform surgical choices.

Investigation and differential diagnoses

Routine imaging in the form of a CT or magnetic resonance imaging (MRI) scan is the baseline required to establish the diagnosis of NPH. Important differential diagnoses to consider include the obstruction of CSF pathways due to a tumour or similar pathology (as per **Box 94.1**), significant cerebral atrophy, evidence of cerebrovascular ischaemic risk burden, and/or neurodegenerative disease. Ventricular enlargement not entirely attributable to cerebral atrophy or congenital enlargement (Evans' index ≥0.3 or comparable measure) should be present (Relkin et al., 2005). The Evans' index is defined as the maximum width of the frontal horns divided by the transverse maximum inner diameter of the skull. An alternative is the bicaudate ratio (ventriculomegaly defined by BCI ≥0.25); this is the minimum intercaudate distance divided by the brain width along the same line (see **Fig. 94.1**).

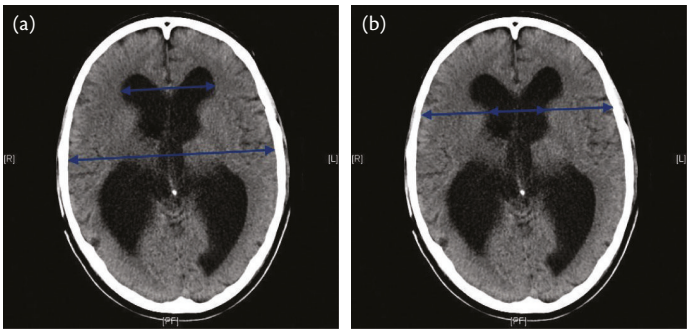

Fig. 94.1 Measurement of ventriculomegaly. (A) Evans' index/ratio: maximum width of the frontal horns of the lateral ventricles divided by the maximal internal diameter of the skull measured at the same level; axial slice in which width of the frontal horns of the lateral ventricles are maximal; significant ventriculomegaly = Evans' index of ≥0.3. (B) Bicaudate index/ratio. Minimum distance between the two caudate apices divided by the brain width along the same line of the caudate measurement: axial slice in which caudate nuclei produced the greatest amount of indentation on the lateral ventricles; significant ventriculomegaly = bicaudate index (BCI) ≥0.25.

Supplementary testing

Guidelines on this matter conclude that a single standard for the prognostic evaluation of iNPH is lacking (Marmarou et al., 2005a). A lumbar puncture 'tap test' with the withdrawal of 40–50 ml of CSF cannot be used as an exclusion test due to its low sensitivity of 26% but has a high specificity of 100%. However, a lumbar puncture is often used as a first line investigative tool to establish that the CSF pressure is within the normal range (5–18 mmHg/7–24 cm H_20) and that no biochemical or microbiological abnormalities are present. The placement of an external lumbar drain to withdraw 300 ml over 5 days has been demonstrated to have a higher sensitivity and specificity—50% and 80%, respectively (Walchenbach et al., 2002). While regarded as gold standard, this method requires an inpatient stay and carries a small risk of infection and nerve root irritation.

CSF outflow resistance measurement (Rout), involving the injection of fluid into a CSF space in the ventricles or lumbar sac (bolus or infusion) is another method of assessing the hydrodynamic state in NPH patients. CSF outflow resistance is calculated based on pressure-volume modelling and has been shown in the Dutch NPH study to have a sensitivity of 46% and a specificity of 87% at an outflow resistance of more than 18 mmHg/ml/min ((Boon et al., 1998). More recent meta analyses revealed a Rout threshold of 12 mmHg/ml/min yielded high accuracy (72.95%), high sensitivity (80.26%), and moderate specificity (46.79%) (Kim et al., 2015). The advantage of this technique is that it only requires a day attendance and can be performed through a preimplanted ventricular reservoir device (see Fig. 94.2B for an example of infusion study data).

Medical management

The option of medical therapies such as serial lumbar punctures and acetazolamide tend to produce limited clinical improvement in this condition. Therefore, surgical intervention is usually recommended on the basis of clinical findings and supportive evidence from supplementary testing.

Surgical management

The natural history of NPH is of progression without treatment, with the majority of patients demonstrating deterioration in symptoms as early as 3 months following initial assessment, although some patients may remain stable for indefinite periods of time.

Considerations for surgical intervention

These include the placement of a shunt or an endoscopic third ventriculostomy. Ventriculoperitoneal (VP) and lumboperitoneal (LP) shunts are by far the preferred options chosen over ventriculoatrial or -pleural varieties. While pressure versus flow-controlled valves may follow surgical preference, the advantage of using programmable designs is clear in the NPH population due to the need to tailor variable responses of these patients to the degree of CSF diversion (please see Chapters 92 and 93 for the technique of shunt insertion and shunt technology).

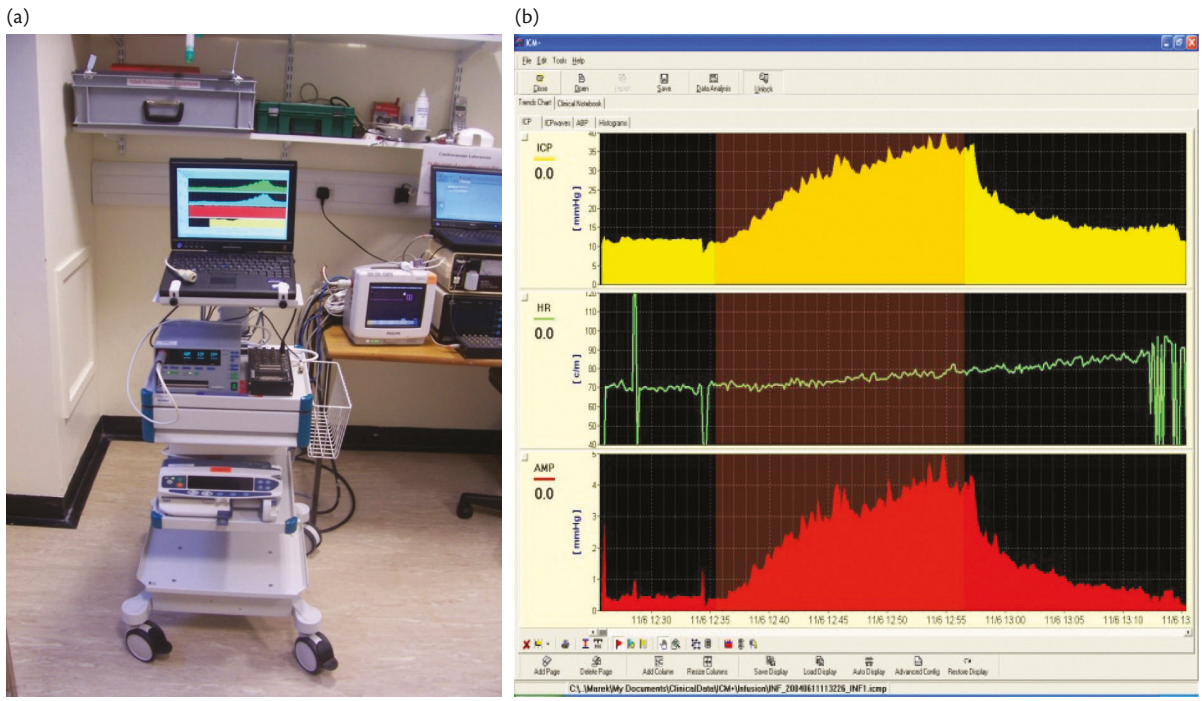

Fig. 94.2 Set-up for CSF infusion study. (A) Mobile unit stack for computerized testing (a computerized infusion test may be performed to interrogate CSF hydrodynamics and extract various parameters). (B) Example of an infusion study data capture. The resistance to CSF outflow (Rout) is calculated as the difference between the end-equilibrium CSF pressure and baseline CSF pressure (i.e. plateau-baseline ICP), divided by the infusion rate.
Courtesy of Dr Zofia Czosnyka and Dr Marek Czosnyka.

The addition of a burr hole reservoir, with the valve in-circuit, may offer the advantage of facilitating CSF interrogation while minimizing the risk of debris being drawn directly into the valve mechanism. Some patients within the NPH spectrum are found to have a form of communicating aqueduct stenosis where there is a relative mismatch between the supratentorial spaces and the fourth ventricle. Although this is a small subgroup, authors have reported good results using the endoscopic third ventriculostomy technique. In a study by Gangemi et al., 72% patients improved with a low complication rate of 4% (intracerebral haemorrhage) (Gangemi et al., 2004). Careful consideration of subgroups, including LOVA as discussed earlier, is crucial to the understanding of surgical options for the individual patient.

Image-guided navigation is not greatly advantageous over anatomical landmarks for cases of significant ventriculomegaly but may be a useful tool in cases of modest ventriculomegaly and to optimize best trajectory for tip placement and to avoid traversing vessels. Optimal placement of ventricular catheters, with or without the aid of image-guided techniques, also serves to minimize longer-term complications of shunt revision due to proximal catheter malfunction and/or blockage. Laparoscopic-guided placement of the distal catheter may minimize the incidence of pseudomeningoceles due to extraperitoneal placement or distal tip migration. This may also be the surgical approach of choice, as joint cases with general surgery colleagues, in cases of known adhesions or false compartmentalization of the abdominal cavity due to previous surgery if preferred over ventriculopleural/atrial approaches.

Risk stratification

In general, the occurrence of complications in the elderly NPH cohort, along with associated premorbidities, may translate into lengthy hospital inpatient stays and the need for rehabilitation if not managed proactively. Methodical preoperative multidisciplinary assessment may be helpful in preventing the unlikely risks of catastrophe, coma, or cardiac event while under anaesthesia by identifying patients at high risk for surgery and providing optimization as necessary. Kiefer's comorbidity index (Kiefer et al., 2006) and other cardiac/global risk scores may be useful in the risk stratification of individual patients by providing an objective assessment of NPH patients with comorbidities, in terms of concurrent vascular, cardiac, and neurodegenerative diseases (see ISHCSF review for a more comprehensive discussion of the influence of comorbidities in iNPH; Malm et al., 2013).

Managing expectations of surgical outcomes is crucial to the discussion of surgical intervention as many patients present late, only have moderate but meaningful improvement levels following lumbar drainage or have significant overlay with other conditions. Favourable predictors of shunt responsiveness include elevated Rout, positive response to external lumbar drainage or repeated lumbar punctures and impaired CBF reactivity to acetazolamide (by SPECT). While comorbidities could be considered unfavourable predictors, age itself may not be a prognostic factor (Halperin et al., 2015).

Postoperative

Complication management

The surgical intervention for NPH carries a risk of infection including meningitis, haemorrhage, seizures, CSF leak, and neurological deficit (i.e. stroke, and shunt malposition or malfunction requiring revision surgery). There is a risk of inadvertent damage to adjacent structures in the neck such as vascular injury, or to the chest, such as pneumothorax, during the tunnelling process for distal catheter placement. Iatrogenic opening of the bowel serosa or mucosa can occur during the attempt to access the peritoneal cavity for distal catheter insertion and necessitates immediate surgical repair. Contamination of the abdominal cavity would be a contraindication for distal shunt placement. The risk of catastrophe is of the order of 1–2% and there is a 3–4% risk of intracerebral haemorrhage (Black et al., 1985). Significant intraparenchymal, rather than tract haemorrhage, may require evacuation of the haematoma, removal of the shunt and insertion of an external ventricular drain but this is a rare subgroup of the overall haemorrhage risk.

More commonly, subdural effusions with or without the presence of haemorrhage are seen although the reported rates range widely from 2% to 17% (Klinge et al., 2005). This may be related to shunt overdrainage or the pre-existing cortical atrophy in some patients. Not all effusions are clinically relevant. Surgical intervention, in the form of burr hole drainage of the chronic subdural haematoma, with or without temporary shunt ligation, is required in the minority of cases. Valve adjustment to reduce drainage for a period of surveillance imaging is usually an effective strategy. Equally important is the risk of underdrainage, requiring general shunt interrogation or valve adjustment for the optimization of symptoms. Patients may also experience complete shunt blockage, breakage, or failure. This may present acutely, even in patients with previously insidious symptoms. Some patients exhibit a heightened sensitivity to shunt valve settings and a subgroup of these may benefit from elective revision to valves with more adjustment setting options. Hashimoto et al. (SINPHONI) 2010 found that, overall, there was a 3% incidence of serious events and a 20% incidence of less serious events (Hashimoto et al., 2010).

Nevertheless, patients with shunt dysfunctions still have potential to improve. Klinge et al. reported that in the European iNPH study, 11% of their unimproved patients had 'silent' shunt dysfunction but could be converted to shunt-responders following valve adjustments (Klinge et al., 2012). While this is made possible by the use of modern variable resistance valves, other options, such as the incorporation of additional antisiphon and antigravity devices into the shunt circuit, require surgical revisions. An average complication rate of 9.8%, such as reported by Marmarou (Marmarou et al., 2005b) can rise to a revision rate of 33% (McGirt et al., 2005) if optimization of surgical outcome is pursued. More strikingly, Pujari et al. found that a revision rate of 53% was still compatible with an improvement rate of 74%, further implying that such optimization was possible to achieve with surgical intervention (Pujari et al., 2008).

Management of intraoperative factors may contribute to the reduction of shunt-related infections. Theatre factors, such as restricting the flow of traffic during shunt implantation, early operative time slot, and short duration of procedure, seniority of the operating team and the use of antibiotic-impregnated catheter options, can be employed to improve surgical outcomes. The spectrum of early to late complications following shunting emphasizes the importance of maintaining regional and national shunt registries to support gaps in clinical information for patients presenting with shunt malfunction.

Outcomes

A review (Klinge et al., 2005) conducted as part of the publication on iNPH guidelines in 2005 concluded that comparisons between NPH studies were difficult due to the differences in the selection criteria for NPH patients, disparate definitions of clinical improvement, varying postoperative follow-up protocols and intervals, and substantial differences in postoperative management. Recommendations made included the following—follow-up at 3, 6, and 12 months, the careful evaluation and treatment of non-responders with regards to shunt malfunction and the use of objective scales in the measurement of improvement. Shorter-term results are more likely to be influenced by shunt-associated risks and longer-term results may be related to concomitant cerebrovascular and vascular diseases. The 1-year postshunt period was thought to be a potential determinant of shunt outcome; beyond this, studies have shown that death and morbidity related to concomitant cerebrovascular and vascular disease influence the clinical effect of shunting.

The panel found that a standard for outcome assessment of shunt treatment in idiopathic normal pressure hydrocephalus was lacking. Several scales are commonly quoted, generally functional grading based on assessments of activities of daily living (ADL) or disability, as well as rating scales for individual components of the triad (Ishikawa, 2014). Groups have also developed their own combination assessments scales, such as the 'Dutch NPH Scale' and that of the European multicentre study in iNPH (see **Table 94.2** for details). In a recent practice guideline report, authors concluded that shunting was possibly effective in iNPH, with more than 80% improvement in gait at 6 months with serious adverse event risk of 11% (Halperin et al., 2015).

Controversies—neuroimaging biomarkers

Current challenges in iNPH are centred upon refining criteria in patient selection for shunting. However, heterogeneity of available methods for grading symptomatology and comorbidities can render it difficult to reproduce the surgical results of larger published series in NPH work. Advances in the development of CSF and neuroimaging biomarkers have the potential to aid in the differential diagnosis of iNPH as well as provide much-needed prognostication and correlation to outcome. Two particular streams of neuroimaging work should be followed with great interest by any iNPH neurosurgeon as the MR techniques would be straightforward to reproduce across centres—quantitative assessments based on key structural features of NPH and diffusion tensor imaging. There is already some evidence that the former is reliable; in a prospective study of one hundred iNPH patients, SINPHONI, an MRI-based diagnosis (evidence of disproportionately enlarged subarachnoid space hydrocephalus, i.e. DESH in which tight high convexity and medial subarachnoid spaces and enlarged sylvian fissures are associated with ventriculomegaly) achieved a favourable outcome in 69–77% patients depending on which outcome grading scale was administered (Hashimoto et al., 2010).

Diffusion tensor imaging (DTI), which is already incorporated into the standard MR sequences for some pathologies, has shown some promise in the differential diagnosis of iNPH vs. other overlapping conditions such as Alzheimer's disease and characterizing the reversibility of acute hydrocephalus. Using DTI, it has been possible to demonstrate different patterns of white matter injury coexisting within NPH, and examine the relative CSF responsiveness to surgical intervention (Keong et al., 2017). Further work to elucidate white matter injury patterns would support early prognostication and prediction of shunt responsiveness. Multimodality correlations, such as with other imaging techniques to interrogate CBF, CSF dynamics, and flow, cerebrovascular reactivity, and brain elasticity, may also be useful in developing biomarkers of potential shunt responsiveness. However, adding layers of complexity to the multistage, multidisciplinary assessment of iNPH, may not always be desirable. While most imaging methods are noninvasive, none could hope to achieve the levels of sensitivity and specificity of an external lumbar drainage test. It could therefore be argued that resources could be best spent in offering this investigation option as widely and as consistently as possible in the work-up for iNPH, even at the stage of differential diagnosis, rather than focusing on analysis-heavy methods which are most likely to be confined to academic centres. Similar issues also apply to the emerging interest in CSF biochemical markers, which require further work on the interpretation of thresholds and more widespread availability as a testing modality.

The most urgent need for refocusing iNPH neuroimaging research is for a consensus of opinion as to the most likely stage in NPH pathophysiology that reversibility of injury can be recognized and the best methodological tools available to examine this in reproducible and quantifiable ways. iNPH represents a unique model of impermanent white matter damage, that if understood, could have implications for the understanding of other types of acute-on-chronic neurodegenerative diseases.

Pseudotumour cerebri syndrome

John Pickard and Nicholas Higgins

Introduction and classification

Following the development of the ophthalmoscope by von Helmholtz in 1851 and the technique of lumbar puncture by Quincke in 1891, Nonne coined the term pseudotumour cerebri in 1904 for cases of papilloedema and raised cerebrospinal fluid (CSF) pressure without mass lesions. The term pseudotumour cerebri syndrome (PTCS) refers to a spectrum of patients who present with raised intracranial pressure without focal neurological disturbance and without evidence on investigation of structural abnormality and who benefit from similar treatments.

The term PTCS highlights the exclusion of an intracranial mass and makes no assumptions about aetiology or mechanism. The addition by Ian Johnston of 'syndrome' to PTC is very helpful and is analogous to the distinction between Cushing's disease and Cushing's syndrome (Johnston et al., 2007). PTCS has been recommended in the recently published revised diagnostic criteria (Friedman et al., 2013).

The term benign intracranial hypertension reflects the absence of sinister intracranial pathology. However, many patients deeply resent the term—their lives are often made miserable with disabling headaches and depression, even though their vision has been preserved.

The most commonly affected group of patients are obese women of childbearing age in whom no cause has been found, hence the diagnostic label of idiopathic intracranial hypertension (IIH). Strictly speaking, IIH should only include cases where there is no known cause once a cause has been rigorously looked for. Many cases labelled as idiopathic have simply not been fully investigated so that published case series of IIH will almost always include secondary causes.

Diagnostic criteria

The diagnostic criteria for PTCS were eponymously ascribed to Walter Dandy following his detailed description of the clinical features of 22 cases in 1937. Subsequently, as a result of new knowledge, these criteria have been modified and now depend on a patient having the symptoms and signs of raised intracranial pressure, a measured increase in CSF pressure, absence of focal neurological signs except for a sixth cranial nerve palsy, normal CSF composition and normal imaging studies (including magnetic resonance venography, MRV). Small ventricles and an empty sella are allowed in the diagnostic criteria. An alternative cause for the symptoms should be excluded and the clinical course except for the effects on vision should be benign.

It is now recognized that papilloedema does not have to be present for PTCS to be diagnosed and the term idiopathic intracranial hypertension without papilloedema is used. In 2013, the diagnostic criteria were further updated and the term PTCS was recommended (**Box 95.1**) (Friedman et al., 2013).

Pathophysiology

The absorption of CSF is a passive phenomenon and, in the steady state, is described by Davson's equation (Davson et al., 1970) which has been modified to include a pulsatile component:

$$P_{csf} - P_{sss} = I_f \times R_{out} (+\text{pulsatile component}),$$

where P_{csf} is CSF pressure, P_{sss} is the pressure in the superior sagittal sinus, I_f is the CSF formation rate and R_{out} is the CSF outflow resistance. Outflow resistance may be measured in patients by measuring the change in CSF pressure as artificial CSF is infused in to the subarachnoid space using a computerized CSF infusion study.

Various mechanisms have been proposed as the basis for PTCS and more than one mechanism may be involved.

Excess CSF production

This is unlikely to be the main mechanism. A doubling of CSF production by itself, in an otherwise normal system, would only increase intracranial pressure (ICP) by 3 mmHg. The only causes of raised ICP due to excess CSF production are choroid plexus villous hypertrophy and choroid plexus papilloma where the choroid plexus is grossly enlarged. Such cases of hydrocephalus require multiple shunts and choroid plexectomy to control ICP because the excess CSF production is so severe. Enlargement of the choroid plexus is not seen in PTCS nor are such drastic procedures required to control ICP. Intracranial infection may increase CSF production but only temporarily.

Box 95.1 Diagnostic criteria for pseudotumour cerebri syndrome

1 Required for diagnosis of pseudotumour cerebri syndrome[a]
- **A** Papilloedema
- **B** Normal neurologic examination except for cranial nerve abnormalities
- **C** Neuroimaging: Normal brain parenchyma without evidence of hydrocephalus, mass, or structural lesion, and no abnormal meningeal enhancement on MRI, with and without gadolinium, for typical patients (female and obese), and MRI, with and without gadolinium, and magnetic resonance venography for others, if MRI is unavailable or contraindicated, contrast-enhanced CT may be used
- **D** Normal CSF composition
- **E** Elevated lumbar puncture opening pressure (≥250 mm CSF in adults and ≥280 mm CSF in children—250 mm CSF if the child is not sedated and not obese) in a properly performed lumbar puncture

2 Diagnosis of pseudotumour cerebri syndrome without papilledema

In the absence of papilledema, a diagnosis of pseudotumour cerebri syndrome can be made if B–E are satisfied, and in addition the patient has a unilateral or bilateral abducens nerve palsy

In the absence of papilledema or sixth nerve palsy, a diagnosis of pseudotumour cerebri syndrome can be suggested but not made if B–E are satisfied, and in addition at least three of the following neuroimaging criteria are satisfied:

1 Empty sella
2 Flattening of the posterior aspect of the globe
3 Distention of the perioptic subarachnoid space with or without a tortuous optic nerve
4 Transverse venous sinus stenosis

[a]A diagnosis of pseudotumour cerebri syndrome is definite if the patient fulfils criteria A–E. The diagnosis is considered probable if criteria A–D are met but the measured CSF pressure is lower than specified for a definite diagnosis.

Cerebral oedema

This mechanism has been proposed, based on the apparently small size of the ventricles in PTCS and on the histological findings on brain biopsy. These studies are fraught with methodological artefact. Modern diffusion-weighted MR scanning has confirmed that there is no evidence of cytotoxic or vasogenic cerebral oedema in PTCS. Furthermore, the preservation of cognitive function and the depth of the cortical subarachnoid space in PTCS found at operation and on MR makes cerebral oedema an unlikely cause for this condition.

Abnormal CSF absorption

There is much experimental and clinical evidence for impairment of CSF absorption in PTCS (Johnston et al., 2007). It was Foley who provided a possible explanation for why the ventricles are not enlarged when the block to CSF absorption is at the level of the arachnoid granulations. He conjectured that, in this situation, where there is no block within the cortical subarachnoid space and free communication between it and the ventricles, excess CSF would be located in the cortical subarachnoid space. Subsequently, his concept has been supported by cisternography studies.

The measurement of CSF outflow resistance (R_{out}) in PTCS is not straightforward. This method assumes that P_{sss} remains constant as CSF pressure increases during a CSF infusion study. Recent measurements of superior sagittal sinus pressure indicate that this assumption is not valid in many patients with PTCS. CSF absorption through the intracranial arachnoid granulations may be inadequate. The spinal arachnoid granulations and other routes of absorption may be recruited in these patients but only at higher baseline pressures.

Abnormal venous drainage

The venous sinuses adjacent to infected ears have long been considered to be the link to raised ICP and otitic hydrocephalus. For example, Janny used direct pressure measurements through a burr hole to demonstrate narrowing of the superior sagittal sinus in patients with PTCS. The narrowings seen in the transverse sinuses on early MR venography studies were often dismissed as MR flow artefacts. Subsequently, meticulous methodological studies using headache-free control subjects have confirmed that these venous changes are genuine and not artefacts. The introduction of retrograde cerebral venography then demonstrated that there was often a significant pressure gradient across the narrowings of the transverse sinus seen in PTCS. Finally, venous stenting of such narrowings has helped to resolve the papilloedema in many patients (Higgins et al., 2002; Higgins et al., 2004; Pickard et al., 2008).

A key issue is the distinction between fixed stenoses and stenoses that reverse at least in part with reduction in CSF pressure after lumbar puncture. Retrograde venography has revealed that sagittal sinus pressure in obese young females with PTCS is not independent of CSF pressure but changes in step with it. Collapsible venous sinuses in PTCS have the potential to introduce a positive feedback loop into the linkage between CSF pressure, CSF absorption, and venous drainage in such a way that as ICP increases, the stenosis gets tighter, venous outflow reduces, and ICP increases even further.

One of the phenomena surrounding PTCS that remains unexplained is how a lumbar puncture may provide symptomatic relief for weeks or months despite the fact that CSF is replaced three times each day. If the narrowing of the venous sinuses is relieved by CSF drainage, the sinuses may remain open until a critical CSF pressure is again reached and this process may take weeks or months.

Steroid metabolism

Venous obstruction does not explain the relationship of PTCS to obesity nor why the CSF pressure increases to initiate the syndrome. Intriguing possibilities are emerging that link obesity to altered steroid metabolism and inflammation. For example, obesity may be linked to abnormalities of 11 beta-hydroxysteroid dehydrogenase type I that is present in both the choroid plexus and the endothelial cap of arachnoid granulations. Hypercoagulability and connective tissue disorders may alter the properties of this endothelial cap. Experimentally, administration of steroids and then withdrawal increases CSF outflow resistance. Sinclair et al. (2010a, 2010b) have

suggested that this mechanism may have dual effects in PTCS both on the choroid plexus with an increase in CSF production and on the arachnoid granulations with impaired absorption.

Clinical

Presentation

The headache of PTCS is unlike the headache of raised ICP due to a brain tumour or acute hydrocephalus which is characterized by early-morning headache made worse by bending down. The headache in PTCS may mimic migraine without aura, chronic daily headache, or tension headache. To complicate matters, many patients may have additional headache secondary to overuse of analgesics. It is instructive to assess which components of the headache are helped by removal of CSF by lumbar puncture. Headache often persists despite resolution of a patient's visual problems after treatment. A minority of patients learn that hyperventilation helps their headache. When they present with hyperventilation and carpopedal spasm, they are too often dismissed as hysterical. Headache may occur without papilloedema and vice versa.

Visual symptoms occur in over half of patients with PTCS and include blurring, obscurations of vision, and lateral diplopia. When PTCS occurs in men it is usually not associated with obesity. Men appear more likely to lose vision early.

Nausea and vomiting are common at the time of first presentation (20%).

Tinnitus is often pulsatile in nature. Pressure on the ipsilateral internal jugular vein may stop the symptom, perhaps because it raises pressure within the transverse sinus and expands an area of reversible stenosis. CSF withdrawal may also reverse such pulsatile tinnitus. If patients complain of pulsatile tinnitus, it is often instructive to compress each internal jugular vein to see whether it relieves the tinnitus temporarily. Other ear symptoms may occur and may be attributable to raised CSF pressure being transmitted to the inner ear through the cochlear aqueduct.

Nerve root symptoms in the arms and legs may occur in a minority of patients presumably due to dilatation of the root sleeves and CSF drainage may ameliorate such symptoms.

CSF rhinorrhoea may occur either spontaneously through an empty sella or via dehiscence of the tegmen tympani or superior semicircular canal. CSF leaks after skull base surgery including trans-sphenoidal pituitary surgery or foramen magnum decompression for Chiari malformations may prove refractory to reoperation until the presence of PTCS is recognized and CSF pressure lowered.

PTCS in childhood is uncommon and may be overdiagnosed if congenital abnormalities of the optic disc (e.g. drusen are not excluded and CSF pressure accurately measured under calm conditions). Children are often not overweight. Where obesity is not an issue, children must be protected against becoming anorexic.

It is important to take an accurate history and perform a general physical examination. Blood pressure should be measured to exclude malignant hypertension and neurological examination undertaken to identify any associated conditions whose treatment might help reverse PTCS (**Box 95.2**).

Box 95.2 Causes of secondary pseudotumour cerebri

Cerebral venous abnormalities
- Cerebral venous sinus thrombosis
- Head injury with fracture over the major cerebral sinuses
- Bilateral jugular vein thrombosis or ligation
- Middle ear or mastoid infection
- Right atrial hypertension
- Superior vena caval obstruction
- Giant arachnoid granulations
- Sinus meningioma
- Arteriovenous fistulae
- Reduced CSF absorption from intracranial infection or haemorrhage
- Hypercoagulable states

Medications and exposures
- Antibiotics: tetracycline, minocycline, doxycycline, nalidixic acid, sulfa drugs
- Vitamin A: hypervitaminosis A, isotretinoin, all-transretinoic acid for promyelocytic leukaemia, excessive liver ingestion
- Hormones: human growth hormone, thyroxine (in children), leuprorelin acetate, levonorgestrel (Norplant system), anabolic steroids
- Withdrawal from corticosteroids
- Lithium
- Chlordecone

Medical conditions
- Endocrine: Addison's disease, hypoparathyroidism
- Hypercapnia: sleep apnoea, Pickwickian syndrome
- Inflammatory: systemic lupus erythematous, Behçet's syndrome
- Anaemia
- Renal failure
- Turner syndrome
- Down syndrome
- Ehlers–Danlos

Others
- Familial
- Space flight

Reproduced with permission from Deborah I. Friedman, Grant T. Liu, Kathleen B. Digre., Revised diagnostic criteria for the pseudotumor cerebri syndrome in adults and children, *Neurology*, Volume 81, Issue 13, pp. 1159–65, Copyright © 2013 Wolters Kluwer Health, Inc.

For example, feeding children excess vitamin A is a cause of PTCS and treatment of iron-deficiency anaemia may reverse PTCS that has proven refractory to conservative and operative management. Inadequate screening for an underlying diagnosis is common.

While many conditions have been associated with PTCS, few studies of such associations meet the criteria for causality, namely that withdrawal of the condition results in reversal of PTCS and reintroduction causes recurrence of PTCS.

Visual abnormalities are present in most patients including papilloedema, visual field changes, reduction of visual acuity, and lateral diplopia. An expert neuro-ophthalmology review is mandatory not only to confirm the diagnosis but also to exclude congenital abnormalities and optic nerve head drusen. Ophthalmological assessment provides an objective baseline for subsequent assessment of progress although it should be noted that papilloedema may not always recur with recurrence of PTCS. If optic atrophy has supervened, even in the absence of papilloedema, patients are still at risk of losing vision.

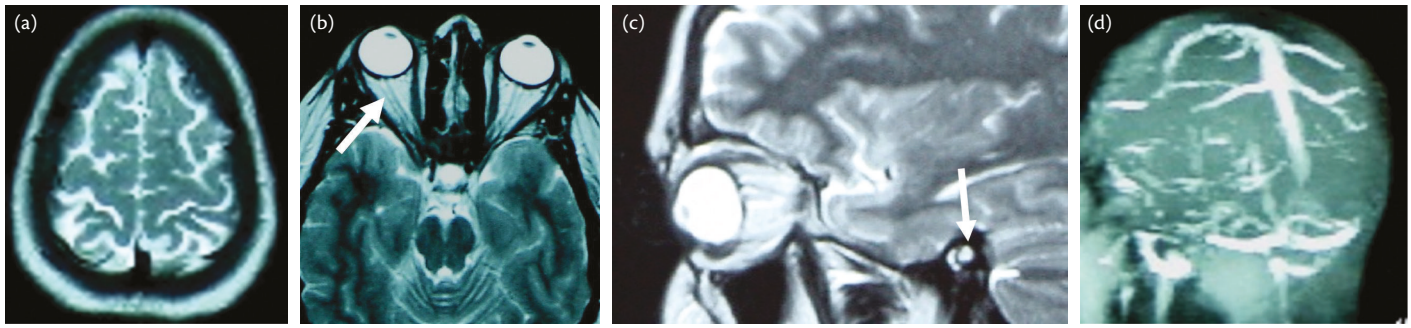

Fig. 95.1 MR features of pseudotumour cerebri syndrome. MR scan of patient with PTCS to demonstrate the various facets of 'meningeal hydrops'. (A) Excess sulcal CSF on the convexity; (B) excess CSF within the optic nerve sheath (arrowed); (C) partial empty sella (arrowed); (D) severe narrowing of the right transverse sinus on MR venography.

Investigations

Urgent computed tomography scanning will exclude a mass lesion and hydrocephalus but will not detect the subtle features of PTCS that a magnetic resonance scan will display. These include dilatation of the optic nerve sheath, with flattening of the posterior part of the globe of the eye, dilatation of the cortical sulci called meningeal hydrops, an empty sella and narrowing of the transverse sinuses (see Fig. 95.1). MRV demonstrated venous changes should not be dismissed as MR flow artefacts. Computed tomography (CT) venography (CTV) is superior to MRV in defining changes in the venous sinuses. Partial reversal of the narrowing of the transverse and other intracranial venous sinuses by CSF drainage may be documented using CTV. Angiography with retrograde venography may be indicated not only to exclude a dural fistula but also to quantify the pressure gradient across any venous sinus narrowing.

Once a mass lesion and a Chiari malformation have been excluded, it is safe to perform a lumbar puncture (LP). LPs in obese patients are often challenging and the source of much psychological trauma. Such LPs should be performed either by or under the immediate supervision of an experienced operator, preferably under X-ray control, together with electronic recording of the pressure for 20 minutes or more. Children may require sedation or general anaesthesia—hyperventilation reduces CSF pressure through lowering of arterial carbon dioxide levels. Consequentially, traumatic lumbar punctures and use of a simple manometer may underestimate the true CSF pressure.

There has been much debate about what the threshold for raised CSF pressure should be, particularly in the presence of morbid obesity and obstructive sleep apnoea. It is essential to appreciate that CSF pressure can fluctuate considerably and in various series, single lumbar puncture measurements have demonstrated pressures of 10–20 mmHg in a minority of patients with all the other features of PTCS. In these patients subsequent continuous monitoring has revealed pressures of over 20 mmHg. See Figure 95.2.

It is therefore misleading to insist on a pressure of over 25 cmH_2O (18 mmHg) in adults and 28 cmH_2O (20 mmHg) in children before making the diagnosis. If there is doubt, continuous monitoring is required aided by a CSF infusion study. The presence of waves of raised pressure during electronic recordings are also valuable indicators of raised CSF pressure. There are a small number of patients who have symptoms and signs of PTCS at CSF pressures of less than 10 mmHg. Where a Chiari malformation is present, ICP monitoring may be

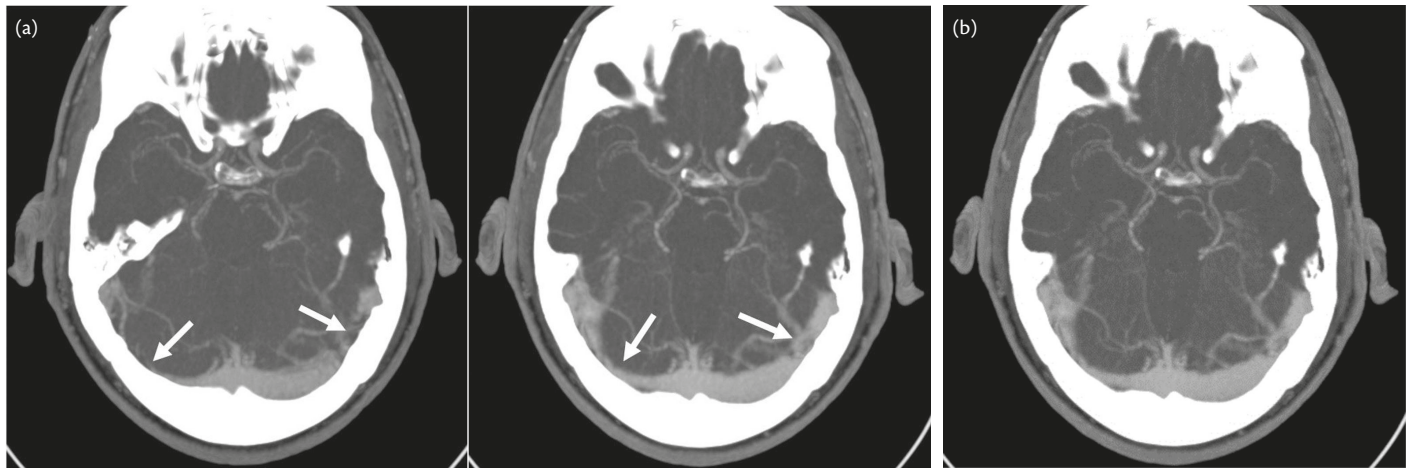

Fig. 95.2 Effect of lumbar puncture on venous sinus stenosis. CT venogram in a case of PTCS with compressible transverse sinuses showing the immediate effects of CSF withdrawal by lumbar puncture. In patients with compressible venous sinuses, this may provide a mechanism for the perpetuation of raised CSF pressures. An insult which increases CSF pressure and compresses the venous sinuses reduces the capacity for CSF resorption and further increases CSF pressure.

required to confirm the diagnosis although characteristic narrowing of the transverse sinuses on venography is indicative of raised pressure.

Protein and glucose concentrations are normal in PTCS although there is often a trend for protein levels to be slightly lower than normal. The search for PTCS-specific biomarkers in the CSF remains at the research stage.

Management

The management plan crucially depends on the rate of visual deterioration. Hence, it is essential that patients with PTCS are managed in a multidisciplinary team setting with clearly defined and carefully audited care pathways and have access to involvement in research. Frustration on the part of patients has led to the formation of specific charities devoted to PTCS/IIH both in the United States and in the United Kingdom. The combination of unsympathetic approaches to weight reduction and analgesic overuse headaches, poorly defined clinical pathways, clumsily performed multiple lumbar punctures, and overdelegation of difficult surgical procedures often leads to psychological problems. It is not surprising that litigation has sometimes followed where there appears to have been an undue delay in managing raised CSF pressure in patients with rapidly deteriorating vision.

Medical management

Causative factors should be looked for and withdrawn or treated. Effective weight reduction through dieting or bariatric surgery improves vision and reduces the severity of headaches (Sugerman et al., 1999). Many patients cannot maintain their diets long-term. A randomized controlled trial of bariatric surgery is now in progress in the United Kingdom.

Drugs

Carbonic anhydrase inhibitors (acetazolamide, topiramate) will help patients with less severe forms of PTCS but many cannot tolerate the side effects. They work by reducing CSF production but can cause renal failure and regular blood chemistry measurements should be obtained. Topiramate is milder but has the advantage of combining a modest carbonic anhydrase blocking effect with appetite suppression and antimigraine properties. It has to be used with care because of potential side effects and some patients just feel unwell on it.

The use of Furosemide has been described but conventional diuretics are little used. Because they cause weight gain, glucocorticoid steroids are now restricted to cases where there is very rapid visual deterioration and are used in combination with an urgent CSF drainage procedure. Octreotide has been used in a few cases, but great care has to be taken in supervising its administration.

Repeated lumbar punctures

Neurosurgeons are often referred patients who have been psychologically traumatized by multiple lumbar punctures, often poorly performed. Too often, only small volumes of CSF are removed. Apart from the often-increasing difficulty in performing such punctures, there is a risk of inducing arachnoiditis. The poor quality of life of patients managed by prolonged use of ineffectual drugs and multiple lumbar punctures should not be underestimated.

Interestingly, removal of large volumes of CSF through a lumbar drain as an inpatient may afford prolonged relief.

Surgical management

Surgical intervention is appropriate for rapidly deteriorating vision and where medical management has failed. Although most patients are young, there may be significant problems with wound healing secondary to smoking and obesity.

Subtemporal decompression and cranial expansion procedures

Subtemporal decompression was the first procedure to be used prior to the introduction of shunts. It has retained a small place in the surgical armamentarium until recently for the rare patient whose PTCS remains symptomatic despite other multiple failed operations (shunts and optic nerve sheath fenestration). It has to be performed with care to avoid the risk of temporal lobe epilepsy.

It should not be offered if a previous foramen magnum decompression has been performed for fear of precipitating brain slump including further tonsillar herniation, syrinx formation, and midbrain distortion.

Through a long pterional scalp flap taking care to avoid trauma to branches of the facial nerve, the temporalis muscle is split in the line of its fibres and its superior attachment preserved. The squamous temporal bone is widely removed from underneath the temporalis muscle down to the floor of the skull base. It is important to avoid making the decompression too small. The dura should not be opened but simply scored in multiple lines to allow it to expand. Anecdotally, it appears that venous stenting may avoid the need for subtemporal decompression.

CSF diversion

Shunt procedures in PTCS are notoriously challenging (Tarnaris et al., 2011). The ventricles are normal or small in size such that image guided placement of a ventricular catheter is wise. There is a tendency for ventricular catheters to intermittently block. Placing a peritoneal catheter into a grossly obese abdomen is not easy with the risk of migration of the catheter tip or variable absorption of CSF. Laparoscopic placement of the abdominal catheter is recommended by some authors. The technique of VP shunt insertion is described in Chapter 89.

Patients with PTCS are often best managed with lumboperitoneal shunts but these too may be complicated by problems with kinking and overdrainage with secondary descent of the tonsils unless a valve with antisiphon properties is used. A lumbopleural shunt that incorporates an adjustable valve and siphon control device is a further

option. This approach has the advantage of connecting two large spaces (lumbar sac and pleural cavity) with the added advantage of negative pleural pressures with each breath to keep the shunt open. A minority of patients will develop refractory pleural effusions and a careful watch has to be kept for secondary tonsillar descent.

The procedure is performed with the patient in a lateral position. As with all shunt procedures every effort must be made to minimize infection risk. This will include reducing the number of people in theatre, preventing unnecessary entry and exit of individuals, prophylactic antibiotics, and a strict sterile technique. The procedure is best performed by two surgeons.

A linear 1.5 cm incision is made through the skin at the midline in the lumbar spine. The dissection is continued down to but not deeper than the tips of the spinous processes at the level of the lumbar fascia. A Tuohy needle is used to perform a lumbar puncture, taking care to ensure that the bevel is then angled so the shunt tubing will pass in a cranial direction. The shunt tubing is inserted through the needle into the lumbar sac and advanced 5 cm. Avoid withdrawing the shunt tubing through the needle or rotating the needle once the tubing is in place, as there is a risk that the tip of the shunt will be sheared off. Once the shunt is in the lumbar sac the needle can be removed, leaving the shunt in place.

A standard open or laparoscopic approach to the abdomen may be used but in very overweight patients in a lateral position it can be surprisingly difficult to find the peritoneum. An alternative is to use the pleural cavity where the approach is just over the upper surface of the rib to avoid the intercostal bundle. The shunt is tunnelled and inserted. The wounds are closed. Postoperative X-rays are useful to confirm the correct positioning of the shunt tubing and to provide a baseline for comparison in the future.

In a patient with recurrent symptoms, detecting whether a lumboperitoneal shunt is blocked can be challenging. Bi-planar X-rays will confirm the position of a shunt and lumbar sac infusion studies may be used to assess outflow resistance but sometimes, exploring and disconnecting the shunt is the only way to definitively confirm the clinical suspicion of shunt blockage.

Optic nerve sheath fenestration

Many ophthalmic surgeons have abandoned optic nerve fenestration because of complications and because it cannot be expected to resolve headaches. Complications that have been described include ocular motility problems, optic nerve haematoma, optic disc infarcts, central branch retinal artery occlusion, sudden postoperative blindness, dacryocystitis and fibrosis (Alsuhaibani et al., 2011).

Venous stenting

Venous stenting is the logical development of the common finding of transverse sinus stenoses. The first case report was published in 2002 and attracted considerable scepticism about the potential risks. In practice and expert hands, it has proven acceptably safe when used for PTCS (Higgins et al., 2003; Ahmed et al., 2011). Stent migration, venous sinus perforation, in-stent thrombosis, and subdural haemorrhage have been described. Such complications are more likely to occur where more difficult lesions are tackled such as areas of thrombosis.

A concept is now emerging that some patients with PTCS have stenoses at the level of the jugular foramen or where the internal jugular vein is wedged between the skull base and styloid process. Some of these patients may be helped by removal of the styloid process and subsequent stenting. See **Figure 95.3**.

Prognosis

Prognosis in PTCS is variable—some patients stabilize after a single lumbar puncture, others have persistent symptoms for many years. A patient's symptoms may improve and then recur years later especially if weight has been lost and then regained again.

Arachnoid cysts

Ruichong Ma and Stana Bojanic

Introduction

Frist described in 1831, arachnoid cysts are cerebrospinal fluid (CSF) filled spaces lined with arachnoid membrane. They account for 1% of all intracranial space occupying lesions and can also be found rarely in the spinal column. The majority of intracranial arachnoid cysts (AC) are found in the middle cranial fossa with a male predilection and a slight preponderance for the left side. With the availability of modern imaging, many more AC are being picked up incidentally in asymptomatic patients. However, symptomatic AC are predominantly found in the paediatric population with patients typically presenting with headaches, rapid head growth, developmental delay, and seizures. Treatment of patients with asymptomatic AC has typically been conservative management with surgery only considered in patients with symptoms. Surgical management remains controversial and includes open techniques, endoscopic fenestration of cyst, or shunting procedures.

Pathology

Classification and formation of arachnoid cysts

AC can be classified as congenital or acquired, secondary to intracerebral haemorrhage or meningitis. AC can be classified by their pathogenesis (i.e. primary or secondary, whether they are symptomatic, or by location). Galassi et al. produced a specific three-part classification of middle cranial fossa AC based on their anatomy and communication with the basal cisterns (**Table 96.1**, **Fig. 96.1**). True AC, however, are deemed to be primary developmental cysts that arise during fetal development. Macroscopically AC membranes look identical to normal arachnoid membranes. However, under the microscope there are several structural differences notably: (1) splitting of the arachnoid membrane at the margin of the cyst; (2) a very thick layer of collagen in the cyst wall; (3) the absence of traversing trabecular processes within the cyst; and (4) the presence of hyperplastic arachnoid cells in the cyst wall, which presumably participate in collagen synthesis (Rengachary and Watanabe, 1981). Intracranial AC are predominantly in the middle cranial fossa, posterior fossa, and frontal regions (**Table 96.2**) and are exclusively associated with normal subarachnoid cisterns. This has led authors to conclude that the formation of AC is due to an anomalous splitting of the arachnoid membrane during folding of the primitive neural tube and formation of the subarachnoid cisterns.

Pathogenesis

The mechanism behind the expansion of AC following formation is not well understood although there are several schools of thought.

Active fluid secretion

In 1964, Robinson reported that there was a difference in consistency in AC fluid as compared to normal CSF (Robinson, 1964). This was subsequently found to be due to a difference in the phosphate, protein, ferritin, and lactase dehydrogenase levels compared to CSF (Berle et al., 2010). A separate ultrastructural and cytochemical study by Go et al. showed that there were structural similarities between AC walls and the neurothelial lining of the arachnoid granulations. This is supported by more recent studies showing a genetic architecture for cyst expansion and quantitative PCR has revealed the Na-K-2Cl cotransporter as a potential mechanism for fluid transport (Helland et al., 2010).

Osmotic gradient

A separate theory suggests that the difference in composition of AC fluid and CSF leads to an osmotic gradient in which water is forced into the cyst. However, for this to have happen there needs to be an initial trigger. In secondary AC, intracerebral haemorrhage or inflammatory reactions can cause this trigger, although there is no evidence for a trigger in primary AC.

Ball and valve mechanism

Studies have shown that small to medium sized AC tend to remain fixed in size and communicate readily with the subarachnoid cisterns whereas in larger or growing cysts there may be a valve in which a unidirectional flow of CSF may occur (Galassi et al., 1982). This is supported by valve-like foldings of the AC wall or intracystic membranes observed intraoperatively.

Table 96.1 Galassi classification of middle cranial fossa arachnoid cysts

Galassi type	Description on CT cisternography	Communication to basal cisterns?
I	Small, limited to anterior middle fossa	Yes
II	Superior extension along Sylvian fissure with displacement of temporal lobe	Yes
III	Large, filling whole middle fossa with displacement of frontal and parietal lobes	No

Reprinted from *Surgical Neurology*, Volume 17, issue 5, Ercole Galassi, Francesco Tognetti, Giulio Gaist, Leo Fagioli, Franco Frank, Giorgio Frank, Ct scan and metrizamide CT cisternography in arachnoid cysts of the middle cranial fossa: Classification and pathophysiological aspects, pp. 363–69, Copyright (1982), with permission from Elsevier.

Fig. 96.1 Illustration depicting the relative size and location of middle cranial fossa arachnoid cysts based on Galassi classification. Type 1, shown in blue are small and limited to the anterior pole of the middle cranial fossa. Type 2, in yellow, extend further posteriorly and superiorly, displacing the temporal lobe, and taking the shape of a parallelogram. Type 3, in red, fill the whole of the middle cranial fossa, in a trapezoidal fashion displacing the frontal and/or parietal lobes.

Table 96.2 Relative distribution of intracranial arachnoid cysts

Location	Frequency
Sylvian fissure	49%
Cerebellar-pontine angle	11%
Supracollicular	10%
Vermis	9%
Sellar/Suprasellar	9%
Interhemispheric fissure	5%
Cerebral convexity	4%
Interpeduncular	3%

Management options

Clinical presentation

The majority of AC, especially in adults, are asymptomatic and are picked up incidentally on imaging. Clinical symptoms in symptomatic patients will be dependent on both the age of the patient and location (Table 96.3). Patients may present following trauma with chronic subdural haematoma or hygroma if the AC wall has burst during the trauma. They can also present acutely with haemorrhage into the AC following trauma or, rarely, as a spontaneous acute subdural haematoma, presumably from the delicate vessels within the wall of the arachnoid cyst.

Middle cranial fossa

The majority of AC are located in the middle cranial fossa or Sylvian fissure (49%). The majority occur in male patients and show a predilection for the left hemisphere (Fig. 96.2A). Symptoms typically arise due to mass effect causing increased intracranial pressure or irritation of the temporal or frontal cortices. Patients can present with headaches, seizures, or contralateral motor weakness. In children, they may present with an enlarging head circumference or asymmetry of the skull/facial bones and even exophthalmos in the extremes due to abnormal development of the sphenoid ridge. Developmental delay is more common in paediatric patients with AC. There is an ongoing debate as to whether temporal AC are linked with psychiatric or neuropsychological disorders.

Posterior fossa

Infratentorial AC account for approximately 20–30% of all AC, with the majority located at the cerebellopontine angle (CPA) (Fig. 96.2B). Symptoms can include headaches from hydrocephalus or gait disturbances from cerebellar compression. Patients with CPA cysts may also develop symptoms from compression of neurovascular structures in the CPA and develop hearing loss, trigeminal neuralgia, diplopia, or bulbar symptoms. The shape of the fourth ventricle, appearance of the cerebellar vermis and the distortion of neural structures help to differentiate posteriorly located AC from an enlarged cisterna magna and Dandy-Walker malformation.

Table 96.3 Signs and symptoms seen in arachnoid cysts based on location

Location	Symptoms
Middle cranial fossa	Headaches, seizures, contralateral weakness, psychiatric or neuropsychological disorders. Children: developmental delay, rapid head growth, failure to thrive, skull/facial deformity
Posterior fossa	Headaches, ataxia, trigeminal neuralgia, hearing loss, ophthalmoplegia, bulbar dysfunction
Frontal	Pituitary dysfunction, visual disturbance, hydrocephalus, bobble-head doll syndrome
Spinal	Myelopathy, radiculopathy

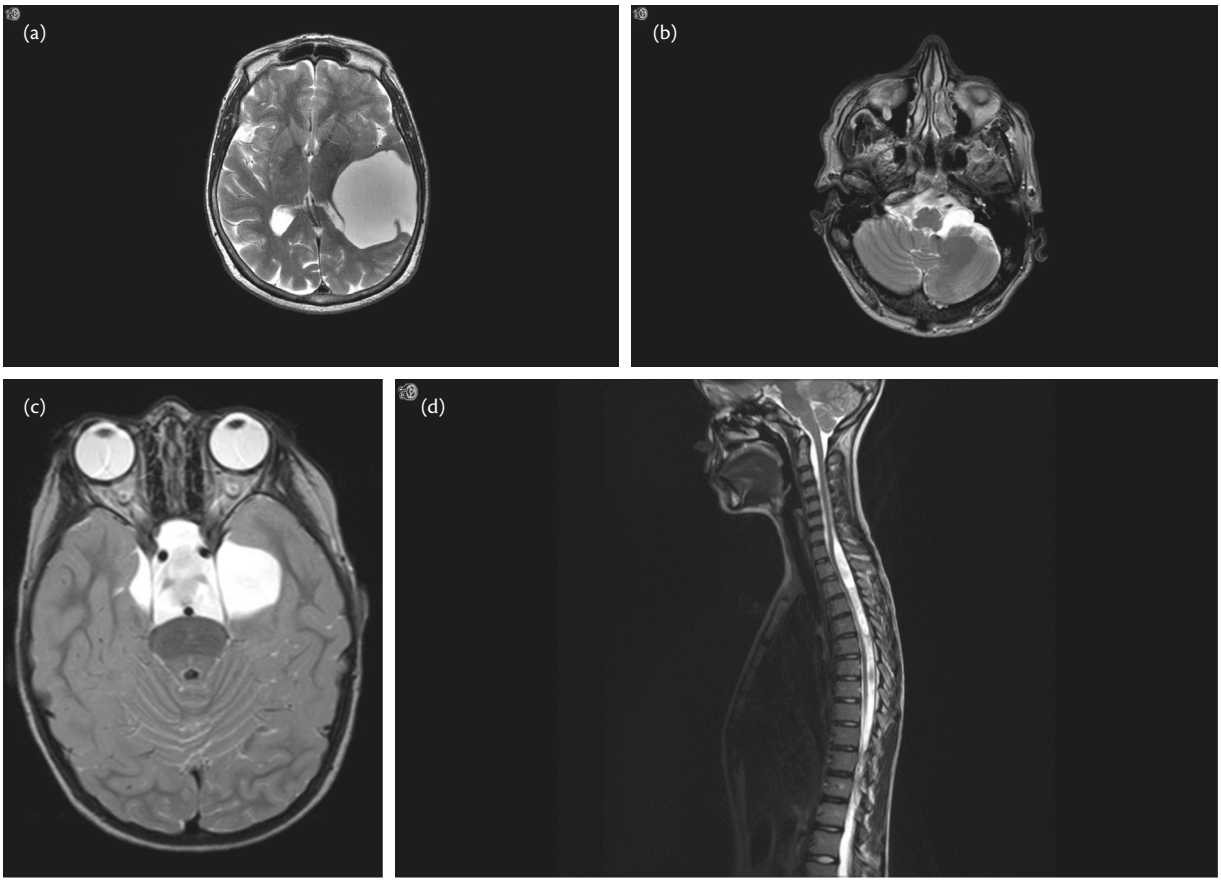

Fig. 96.2 T2-weighted MRI of patient with (A) left middle cranial fossa arachnoid cyst, (B) left cerebellopontine angle arachnoid cyst, (C) suprasellar arachnoid cyst, (D) Spinal arachnoid cysts from T1 to T3 with anterior displacement of the spinal cord.

Frontal

Sellar or suprasellar cysts arise in the basal subarachnoid space, closely approximated to the optic nerves, pituitary gland, hypothalamus, and mesencephalon (Fig. 96.2C). Thus patients may show signs of pituitary insufficiency and visual loss from compression of such structures. Occasionally, if the AC is very large, it may also cause obstructive hydrocephalus from compression of the third ventricle. In such circumstances, patients may develop a bobble-head doll syndrome showing involuntary back and forwards bobbing of the head at 2–3 Hertz.

Intra- and periventricular

The rare intraventricular AC may need high definition magnetic resonance imaging (MRI) to define the cyst wall. Suprasellar cysts compression the third ventricle anteriorly can be mistaken for a triventricular hydrocephalus with 'ballooning' of the third ventricle and be inappropriately treated by a ventriculoperitoneal (VP) shunt. Those arising within the quadrigeminal cistern similarly may compress the posterior third ventricle and aqueduct.

Spinal

Spinal AC (Fig. 96.2D) typically present with signs and symptoms of either myelopathy (ataxia, progressive spastic paralysis with a sensory level), or radiculopathy (neuralgia or localized motor-sensory deficits). This is due to compression of the spinal cord or exiting nerve roots. Occasionally, back pain can be the only presenting symptom leading to investigation.

Investigation

Patients presenting with neurological symptoms should have a detailed history and examination performed. The diagnosis of arachnoid cyst is one made on imaging, the mainstay of which is MRI. They are typically hypointense on T1 and hyperintense on T2, much like CSF. Modern phase contrast MRI and functional MRI are not only capable of showing structural abnormalities but also delineate CSF-flow patterns and any changes in functional organization of the brain. Computed tomography (CT) cisternography, where contrast is injected into the subarachnoid space with subsequent time-lapse CT scans is now reserved for the rare cases of diagnostic uncertainty. Differential diagnoses of AC are many and can be found in Table 96.4.

Asymptomatic AC are treated conservatively with serial imaging to ensure stability. Patients presenting as an emergency with acute obstructive hydrocephalus will require urgent surgical intervention. Patients with chronic subdural haematomas will require primary treatment of the haematoma but not necessarily of their underlying AC. Conversely, patients with AC and subdural hygromas at presentation do well with medical treatment with acetazolamide, avoiding the need for surgery. For symptomatic patients, treatment is usually offered in the form of surgery except if headache is the only symptom. These patients must be treated with caution, as the causes of headaches

Table 96.4 Differential diagnoses of arachnoid cysts and their differences on imaging

Differential diagnosis	Difference on imaging
Enlarged CSF space (e.g. mega cisterna magna)	Enlarged anatomically correct CSF space
Epidermoid cyst	Heterogenous signalling on MRI flair Restricted diffusion More lobulated
Cystic tumours: • **Pilocytic astrocytoma** • **Haemangioblastoma**	Intra-axial Often has enhancing component
Non-neoplastic cysts: • **Neurenteric cysts** • **Neuroglial cysts** • **Porencephalic cyst**	Intra-axial Communication with foregut derivatives (neurenteric cysts) Usually surrounded by grey matter (neuroglial cysts) or gliotic (porencephalic cysts) tissue
Infectious: • **Hydatid cyst** • **Neurocysticercosis**	Cysts in other parts of the body, e.g. liver (hydatid cysts) Usually small and multiple (neurocysticercosis)

are many-fold and all other causes of headache must be explored before surgery is offered. There is still controversy as to whether such patients receive good symptom relief from surgical management of AC.

Surgical approaches

Shunting

Much like in hydrocephalus, a shunt can be placed into the cyst to drain it into another body cavity to allow for reabsorption of the CSF. Typically, these drain either into the peritoneum or the subdural space. This is the least invasive procedure and confers the lowest perioperative risk. However, it is the least successful in the long term with a repeat operation required in 26% of patients (Helland and Wester, 2006).

Open approaches

Treatment of AC has historically been through open approaches through a craniotomy. The cyst wall can be excised or marsupialized to open up flow into the subdural space. Alternatively, most techniques revolve around fenestration of the cyst to allow CSF flow back into natural CSF spaces (i.e. the basal cisterns or ventricular system). Some surgeons would recommend fenestration of the cyst into two CSF spaces in order to allow CSF flow through the cyst in order to keep the stomata open and prevent recurrence/treatment failure.

Endoscopic approaches

More recently, endoscopic techniques have been utilized to perform endoscopic fenestration of the medial cyst wall into both the basal cisterns or ventricles (Fig. 96.3). These newer techniques reduce the size of the craniotomy required, with many operators performing surgery through a single burr hole. Some surgeons also utilize neuronavigation to help navigate through what can potentially be difficult anatomy, especially if the cyst wall is thickened. There is still ongoing debate with regards to the optimal treatment modality and this will be discussed next.

Ideally, whenever possible, a 'bipolar' fenestration, that is, a combined cystoventriculostomy in addition to a cystocisternostomy for third ventricle-associated AC ensures optimum CSF flow (Kirollos et al., 2001) (Fig. 96.3).

Management of spontaneous or post-traumatic haemorrhage with an underlying arachnoid cyst

When clinically indicated, in most cases evacuation of subdural haematomas through burr holes or less commonly by a

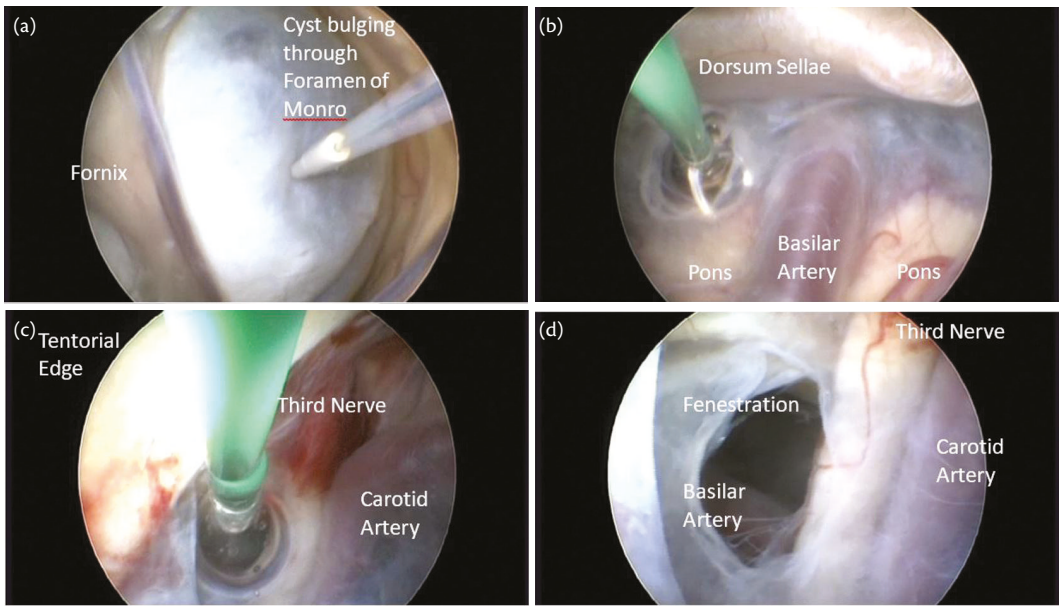

Fig. 96.3 Intraoperative view of endoscopic fenestration of a suprasellar/third ventricular arachnoid cyst. (A) Cystoventriculostomy of the cyst dome at the foramen of Monro into the lateral ventricle, (B) cystocisternostomy at the base of the cyst to the prepontine cistern just lateral to the basilar artery. Intraoperative figure of endoscopic fenestration of a middle fossa arachnoid cyst to the interpeduncular and prepontine cisterns (C) widening the fenestration using a Fogarty balloon just posterior to the third nerve, (D) a view of the basilar artery in the basal cisterns.

minicraniotomy is the initial treatment. In many reports subsequent treatment of the underlying arachnoid cyst was not necessary.

Spinal AC are treated surgically predominantly through an open dorsal approach.

Postoperative

Outcomes

Outcomes following surgery for AC are very favourable with 76–95% of patients achieving good long-term success following open techniques and up to 95% of patients following endoscopic techniques (Helland and Wester, 2006; Johnson et al., 2011). Failure rates are not significantly related to location of cyst although frontal AC tend to achieve better results, especially through endoscopic techniques. The long-term success rate for shunting procedures is lower at 74% (Helland and Wester, 2006) reflecting the long-term problems associated with shunts.

Complications

Operating on AC carries an overall complication rate of 16.9%, and a reoperation rate of 7.2% (Helland and Wester, 2006). These complications seem to almost exclusively happen in patients with temporal AC. The major complication following surgery and treatment of intracranial AC include subdural hygromas, with an incidence of 4–6% in open microsurgical techniques and 9% following endoscopic techniques for middle cranial fossa AC (Cincu et al., 2007; Johnson et al., 2011) and a 6% risk CSF leak (Pradilla and Jallo, 2007). There is a small additional risk of intraoperative haemorrhage during endoscopic techniques, which necessitates conversion to open microsurgical techniques. Although the operative risks involved with shunting procedures is thought to be lower, the immediate complication rate was not significantly lower (Helland and Wester, 2006).

Controversies

A large proportion of AC are incidental. Careful selection for treatment especially in the presence of unrelated headaches and other vague symptoms is important.

There still remains controversy among neurosurgeons regarding the optimum surgical technique for treating AC (Table 96.5). Advocates of shunting techniques state that it is a less invasive technique that conveys the lowest operative risk to the patients while providing good control of the cyst volumes through pressure-controlled systems. Data shows that resection or fenestration of AC do not confer a significantly increased risk of immediate complication and any complications arising are relatively minor or temporary (Helland and Wester, 2006). Many surgeons are now able to show extremely good long-term results from both open and endoscopic techniques with long-term success rates of up to 95% (Johnson et al., 2011) compared to 74% for shunt procedures. Many patients are children at presentation and will inevitably require multiple shunt revisions throughout their lifetime, whereas treatment of the cyst itself is potentially curative. For this reason, the majority of neurosurgeons will opt for surgical treatment of the cyst as the first line of treatment with shunting as a second line treatment.

Table 96.5 Pros and cons of various surgical techniques used to treat arachnoid cysts

Operative technique	Pros	Cons
Shunting	Minimally invasive, quick	Lower chance of long-term success, risk of shunt malfunction/infection
Open microsurgery	Low rate of recurrence	Need for craniotomy, prolonged surgical time, higher risk of infection
Endoscopic surgery	Low rate of recurrence, minimally invasive	Higher risk of intraoperative bleeding, higher risk of post-op subdural hygroma, specialist experience required

Sport participation in arachnoid cyst patients

Participation in sports is still a controversial issue in patients with AC. There are a cohort of neurosurgeons who believe that the presence of AC increases the risk of haemorrhage and brain injury following trauma and hence contact sports should be avoided. To support this, there are numerous case reports and case series in the literature of patients with AC who have sustained sports-related structural brain injury. The most common injury seen is a post-traumatic subdural hygroma thought to be due to tearing of the cyst wall creating a one-way valve. There is also an increased risk of developing subdural haematomas although bleeding directly into AC is a rare occurrence. However, it is important to recognize that all contact sports inherently carry a risk of developing traumatic brain injury even in the absence of AC, although some case reports in the literature do describe injury following low-impact trauma in patients with AC not normally associated with brain injury. In addition, patients presenting with AC-related structural brain injury tended to have a later presentation to hospital. There is an inherent publication bias with these case reports, in that in order to be publishable, the particular case typically manifest the following: (1) novel presentation; (2) surgical management; and (3) good outcomes. It is unclear how many patients presenting in a standard fashion are treated conservatively with good effect. A recent prospective cohort study of 185 children diagnosed with AC (Strahle et al., 2016) shows that 112 patients participated in 261 different sports for a total of 4410 months. In this cohort only two patients suffered from symptomatic subdural hygromas with no neurological injury. Both hygromas were treated conservatively and settled with time. However, most of these patients were young children participating in low-level, low-impact sports. It would be expected that older children and adults participating in higher-level sports will risk higher impacts and have increased rates of traumatic brain injury.

To call an activity 'safe' inherently involves a judgement call against a subjective level of acceptability, as no sport is truly 'safe' if the standard is of absolute safety (i.e. there is no risk of injury). Such a standard is not applied to the general population and should therefore not be applied to patients with AC. There is an increased risk of structural brain injury in patients with AC through participation in sports, although it is still a rare occurrence with predominantly good outcomes. Each patient should be counselled individually and the choice to continue to participate in sports should be made in partnership between the physician and patient.

Microbiology

Walter A. Hall

Introduction

Infection of the central nervous system (CNS) can be due to various antimicrobial agents that include viruses, bacteria, fungi, and parasites. Several factors determine whether or not a CNS infection develops such as the virulence of the organism, the status of the host's immune system, the size of the infectious inoculum, and the presence or absence of inherent or medication-related immunosuppression (Hall, 2008). The ability to detect the presence of a CNS infection has been greatly aided by the availability of imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI) that can demonstrate the intracranial compartment. These same radiological techniques also allow for the response to treatment to be monitored. Newer image-guided surgical approaches using neuronavigation or intraoperative-MRI allow neurosurgeons to access remote regions of the brain that harbour infection which can expedite the identification of the causative agent leading to the prompt initiation of appropriate treatment. Rapid isolation of the organism combined with surgical decompression of neural elements, if necessary, can help to improve clinical outcomes and reduce neurological morbidity and mortality. The organisms that cause infection after neurosurgery can be significantly different from the aetiologic agents found in spontaneous CNS infection. Our focus will be on those organisms that require neurosurgical intervention either for identification, the relief of brain compression causing neurological symptoms, or that are the result of having had a surgical procedure involving the CNS. The primary infectious processes that affect the CNS are meningitis (**Fig. 97.1**), encephalitis (**Fig. 97.4**), cranial epidural abscess (**Fig. 97.2**), subdural empyema (**Figs. 97.3 and 97.4**), and brain abscess (**Fig. 97.5**).

Classification

Bacteria

Bacteria are probably responsible for the majority of CNS infections for which neurosurgeons are consulted. Those bacteria that represent the patient's endogenous skin flora that leads to the majority of postoperative neurosurgical infections are *Staphylococcus aureus* and *Staphylococcus epidermidis*. Hospital-acquired pathogens that include Gram-negative bacilli and fungi are often resistant to multiple antimicrobial agents making their treatment difficult. Those bacteria that are often responsible for spontaneous meningitis are *Haemophilus influenzae* type b, *Neisseria meningitidis, Streptococcus pneumoniae*, and *Listeria monocytogenes*. Postoperative and traumatic cerebrospinal fluid (CSF) leaks are known sources for meningitis with half of the cases caused by the Gram-negative bacilli *Pseudomonas aeruginosa, Klebsiella* species (sp.), and *Escherichia coli. Mycobacterium tuberculosis* can be a cause of lepto-pachymeningitis and can also present as calcified intraparenchymal lesions representing microabscesses.

Shunt infections are most commonly due to coagulase-negative *Staphylococcus epidermidis* (Naradzay et al., 1999). Other bacteria known to cause shunt infections are *S. aureus*; the Gram-negative bacteria *Acinetobacter baumannii, Escherichia coli, Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*; the diphtheroid *Propionibacterium acnes*; and anaerobes (Sacar et al., 2006). Immunocompromised patients can develop shunt infections due to *Candida* sp. Polymicrobial shunt infection can occur in 11% to 20% of cases (Grandhi et al., 2014).

Aerobic and anaerobic organisms, particularly *Streptococcus milleri*, from the paranasal and otogenic sinuses can cause cranial epidural abscesses or subdural empyemas. Staphylococci and Gram-negative bacilli can cause cranial epidural abscess and subdural empyemas after neurosurgery (Hall, 2008). Anaerobic organisms such as streptococci and *Bacteroides* sp. from an otogenic or dental source are those most responsible for the development of brain abscess. Following head trauma, brain abscess due to aerobic isolates such as *S. aureus*, streptococci, and Gram-negative bacilli are common (Hall, 2008). *Staphylococcus* sp. brain abscess are most common in intravenous drug users and after craniotomy as a result of inoculation from contaminated skin (Kim and Hall, 2014).

Viruses

Viral infections of the CNS can cause meningitis, encephalitis of the brain, and transverse myelitis of the spinal cord. Viral meningitis is relatively common and does not usually require neurosurgical intervention whereas encephalitis is much less common, far more serious, and may require neurosurgery. Although there are numerous viruses the can affect the CNS, those where neurosurgery may be consulted are limited to herpes simplex virus

Fig. 97.1 Axial CT scan of the head in a 1-month-old newborn boy showing hydrocephalus and diffuse enhancement around the brain stem indicative of meningitis that was found to be due to *Escherichia coli*.

Fig. 97.3 Axial non-contrast CT scan of the head showing a subdural empyema over the left cerebral hemisphere extending into the interhemispheric fissure with associated mass effect. The source of the infection was bilateral maxillary sinusitis due to *Streptococcus milleri*.

type 1 or 2 (HSV-1 or HSV-2), human immunodeficiency virus (HIV) type 1 or 2, and the human JC polyomavirus. Herpes simplex virus (HSV) causes 2% to 5% of encephalitis in the United States (Domachowske et al., 2014) usually due to HSV-1 in more than 90% of cases (Whitley, 2006). The virus has a predilection for the temporal lobes and subfrontal cortex which is best seen on MRI as an area of increased signal on diffusion-weighted imaging. The fact that the virus crosses the Sylvian fissure discriminates this infectious process from an intrinsic brain tumour. The

HIV causes acute viral meningitis in 5% to 10% of patients with the acquired immunodeficiency syndrome (AIDS), either when the virus is acquired or during the seroconversion phase (Fukuta and Byers, 2014). When HIV infects the brain, it can cause encephalitis and involvement of the spinal cord can result in acute transverse myelitis. In immunocompromised patients and in up to 25% of those with AIDS, the JC virus causes progressive multifocal leukoencephalopathy (PML) (Berger and Levy, 1993).

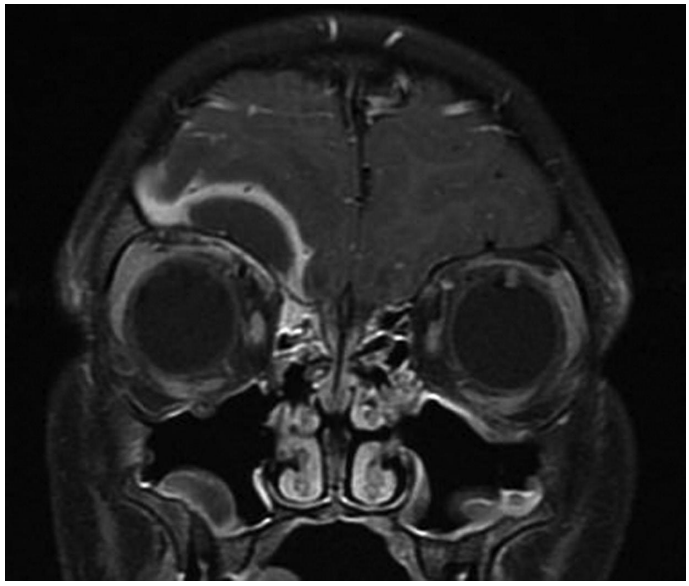

Fig. 97.2 Contrast-enhanced coronal T1-weighted MRI scan of the brain demonstrating a cranial epidural abscess due to chronic sinusitis which is also visible in a 10-year-old boy. Because of the prior administration of antibiotics before sinus cultures were obtained, the causative organism was never identified.

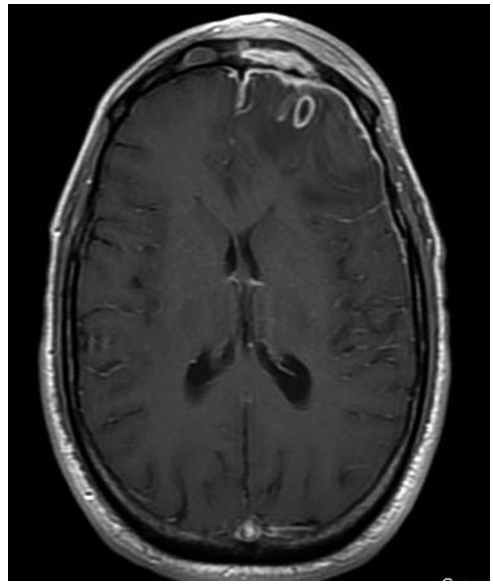

Fig. 97.4 Axial contrast-enhanced T1-weighted MRI scan of the head revealing a left frontal subdural empyema with encephalitis from frontal sinusitis which is also visible. The organism responsible for the infection was *Staphylococcus epidermidis*.

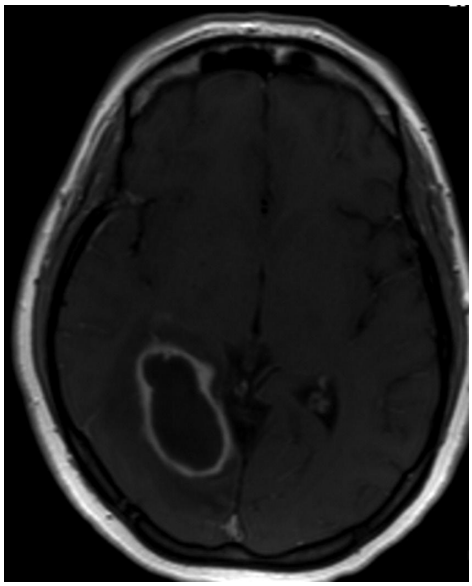

Fig. 97.5 Axial contrast-enhanced T1-weighted MRI scan of the head revealing a right occipital brain abscess. *Bacteroides fragilis* was cultured from the purulent collection that was thought to have resulted from poor dentition.

Fungi

Fungal infections of the CNS are usually manifest as meningitis or brain abscess. Clinically significant fungal infections of the CNS are usually identified in patients with altered immune function that is due to AIDS, diabetes mellitus, medication-induced immunosuppression (i.e. corticosteroids, chemotherapy, antiorgan transplant rejection medications, and broad-spectrum antibiotics), cancer, neutropenia, thermal injuries, collagen vascular diseases, hepatic disease, intravenous drug use, chronic pulmonary disease, Cushing syndrome, dehydration, ketoacidosis, anaemia, leukopenia, malnutrition, splenomegaly, chronic granulomatous disease, and prior craniotomy (Hall and Kim, 2014). Meningitis is most commonly caused by *Cryptococcus neoformans* and *Cryptococcus gattii*, whereas brain abscess is most often due to *Aspergillus* sp. Because it spreads through the bloodstream, *Candida albicans* can lead to the formation of micro- and macro-abscesses. Basilar leptomeningitis resulting in CSF obstruction and hydrocephalus is the most common form of CNS involvement by *Coccidioides immitis*. *Histoplasma capsulatum* can present either as a basilar leptomeningitis with hydrocephalus or as intraparenchymal small miliary granulomas or large histoplasmomas. Chronic meningitis or intracerebral blastomycomas are caused by *Blastomyces dermatitidis*. Vasculitis of the intracranial vasculature leading to mycotic aneurysm formation can be caused by *Candida albicans, Coccidioides immitis, Aspergillus fumigatus*, and *Mucor* sp. *Aspergillus* sp. and mucormycosis are aggressive fungal infections that usually involve the brain through the medium- and large-sized arteries resulting in the development of a mycotic aneurysm or by presenting with an intracerebral haemorrhage or ischaemic infarct from vascular occlusion (Hall and Kim, 2014). Infarcted brain tissue serves as the perfect medium for propagation of the fungus. If the proximal large arteries are invaded by fungi the clinical presentation may be a subarachnoid haemorrhage. *Scedosporium apiospermum* is the asexual form of *Pseudallescheria boydii* and usually presents as a brain abscess or rarely as meningitis (Hall and Kim, 2014).

Parasites

Parasitic involvement of the CNS is primarily due to two helminth tapeworms that cause cysticercosis and echinococcosis. Because of the worldwide increase in international travel to areas where certain parasites are endemic, these infections are becoming more commonplace. Cysticercosis is the most common parasitic disease of the CNS and is caused by the pork tapeworm *Taenia solium*. The tapeworm *Echinococcus granulosus* is responsible for the cystic form of CNS echinococcosis or hydatid disease (Akhaddar and Boucetta, 2014). Cysticerci are more commonly found in the brain parenchyma than in the subarachnoid space and cause encephalitis and seizures. Basal meningitis occurs when the meninges are involved, and hydrocephalus can result when the cysts obstruct the aqueduct of Sylvius or the fourth ventricle.

Cystic hydatidosis is the most common form of this disease to affect the brain and spine in humans. Hydatid cysts are usually solitary in the brain and the spine, where the vertebral body is more often involved in echinococcosis than in cysticercosis (Hall, 2015). In hydatid disease, symptoms due to the compression of neural elements are most commonly related to where the cyst is located in the brain or spine.

Amoebiasis is a parasitic disease caused by the protozoa *Naegleria fowleri, Acanthamoeba* sp., and *Balamuthia* sp. Free-living amoebas tend to cause encephalitis or meningoencephalitis. Cerebral amoebiasis has become a more recent concern of the medical community because it can develop in both normal and immunocompromised individuals and is generally fatal. Those conditions that are associated with the development of cerebral amoebiasis in immunocompromised individuals include AIDS, liver disease, diabetes mellitus, organ transplantation, renal failure, alcoholism, intravenous drug use, and the administration of corticosteroids or chemotherapy (Hall, 2012b).

Diagnostic techniques

Obtaining appropriate specimens is essential for determining the causative organism and assisting in the choice of effective antimicrobial therapy. Intraoperative cultures are most useful for diagnosing a hardware infection that involves neurosurgical implants although superficial cultures can be difficult to interpret because the most common offending organisms are normal skin flora (Fukuta and Byers, 2014). Ideally, the initiation of antimicrobial therapy should be delayed until adequate specimens have been collected unless the delay poses an unacceptable risk for the patient.

Cerebrospinal fluid

If postoperative meningitis is suspected, a lumbar puncture can be performed provided there is no evidence of mass effect on imaging studies that could potentially lead to a herniation syndrome. The opening pressure of the cerebrospinal fluid (CSF) can be elevated in meningitis and the colour of the fluid may be cloudy or turbid instead of being clear. The white blood cell (WBC) count can be elevated above the normal value of 0–5 mm^3 with a predominance of

neutrophils being present. A CSF glucose to blood glucose ratio of less than 0.5 is considered abnormal and the CSF protein level can be elevated. Around 1–2 ml of CSF should be sent for bacterial culture and 5–10 ml should be sent for acid-fast bacillus or fungal culture. The CSF culture is considered the diagnostic gold standard, however if prior antimicrobial therapy has already been started the chance of identifying the offending organism falls to less than 50% (Fukuta and Byers, 2014). Nucleic acid amplification tests such as the polymerase chain reaction (PCR) in the CSF may be useful for excluding bacterial meningitis or when antibiotic treatment has been started and the culture results are negative. Gram stain of the CSF will demonstrate bacteria in 50% of *L. monocytogenes* or Gram-negative bacilli cases and in up to 90% of *S. pneumoniae* cases (Fukuta and Byers, 2014). In the patient with a suspected ventriculoperitoneal shunt infection, CSF specimens obtained by valve puncture or from the ventricular catheter are more likely to yield microorganisms than CSF that is collected through a lumbar puncture. To detect the acid-fast mycobacteria in tuberculous meningitis, the Ziehl-Neelson and the Kinyoun stains are used.

In HSV encephalitis, the CSF can show a mononuclear pleocytosis, red blood cells suggestive of haemorrhagic necrosis, decreased glucose levels, and an elevated protein level (Domachowske et al., 2014). Polymerase chain reaction is the gold standard for HSV and HIV detection in CSF. Because HSV is rarely cultured from the CSF, a brain biopsy is often required to make the diagnosis. An additional role for neurosurgery in HSV encephalitis may be the performance of an emergency cranial decompression in the face of uncal herniation that occurs in a delayed manner of more than 10 days (Domachowske et al., 2014). In PML, the CSF is usually normal and the detection of the viral DNA by PCR is the diagnostic test of choice (Domachowske et al., 2014). Detection of protein 14-3-3 in the CSF is highly specific and sensitive for the diagnosis of classic Creutzfeldt–Jakob disease (CJD) (Defebvre et al., 1997).

Candida albicans can be detected in the CSF using a PCR-based test and by measuring a *Candida*-specific mannan antigen titre (Hall and Kim, 2014). Complement fixation antibodies to cryptococcal antigen, *Histoplasma* antigen, *Aspergillus* galactomannan, and *Coccidioides* sp. can identify fungal infection in the CSF. An India ink preparation can detect *C. neoformans* in the CSF and if infected brain tissue is obtained through surgery a Gomori methenamine silver stain may be used to demonstrate *Aspergillus* sp. or *Mucor* sp. (Hall and Kim, 2014).

The CSF in cysticercosis and hydatid disease is usually unremarkable and should not be sampled in the presence of significant intracranial mass effect in order to prevent a herniation syndrome. The CSF in amoebic meningoencephalitis can be haemorrhagic and demonstrate an elevated WBC count. Amoeba can be identified occasionally in the CSF on a wet mount and antibodies and PCR can be used to detect the infection in CSF (Hall, 2012b). Giemsa or Wright stains of the CSF should be used to demonstrate the trophozoites in primary amoebic meningitis (Fukuta and Byers, 2014).

Blood

C-reactive protein (CRP) can be significantly elevated in virtually all cases of intracranial infection. The erythrocyte sedimentation rate (ESR) is also usually elevated in CNS infections but not as frequently as is the CRP. The ESR and the CRP levels can also be used to follow the patient's response to antimicrobial therapy. Blood cultures can be useful in diagnosing a ventriculoatrial shunt infection although they are unlikely to be helpful in diagnosing the presence of a ventriculoperitoneal shunt infection.

Serum serology can be used to diagnose coccidioidomycosis and antigen tests for *Cryptococcus* sp. and *H. capsulatum* can establish the diagnosis in disseminated disease (Hall and Kim, 2014). Enzyme-linked immunoelectrotransfer blot is the serodiagnostic test of choice in cysticercosis with a sensitivity of 98% and a specificity of 100% although the sensitivity is only 30% in single cerebral lesions (Akhaddar and Boucetta, 2014). The serologic diagnostic test of choice for CNS echinococcosis is based on the detection of immunoglobulin G antibodies to hydatid cyst fluid-derived native or recombinant antigen B subunit on an enzyme-linked immunosorbent assay (ELISA) or immunoblot assay (Akhaddar and Boucetta, 2014).

Other tests

Herpes simplex encephalitis can demonstrate paroxysmal lateral epileptiform discharges on electroencephalography (Domachowske et al., 2014).

TORCH infections

Perinatal infections can result in congenital anomalies. Infections acquired *in utero* or during delivery can lead to fetal or neonatal mortality and early or late childhood morbidity. Five common infections with similar presenting features such as rash and ocular findings were categorized together and designated TORCH (Toxoplasmosis, Other (syphilis, enteroviruses, varicella-zoster virus, and parvovirus B19), Rubella, Cytomegalovirus (CMV), and Herpes simplex virus) infections (Stegmann and Carey 2002). Of the five virus types comprised in the TORCH acronym, CMV has emerged at the most common congenital viral infection. These infections cause mild maternal morbidity but can have serious consequences for the fetus and despite treatment of the maternal infection there is no effect on fetal outcome (Stegmann and Carey, 2002).

A high index of suspicion for perinatal infection is essential for a timely diagnosis and the rapid initiation of appropriate treatment. Clinical manifestations that are suggestive of a congenital TORCH infection can include macrocephaly, seizures, hearing loss, cataracts, rash, hydrops fetalis, congenital heart disease, hepatosplenomegaly, jaundice, and thrombocytopenia. These clinical findings are not limited to TORCH infections and can be seen in other diseases and conditions. The classic triad for congenital toxoplasmosis is chorioretinitis, hydrocephalus, and intracranial calcifications however most infants with the disease are asymptomatic without apparent abnormalities at birth. Herpes simplex virus infection in the newborn has three patterns of presentation: localization to the skin, eyes, and mouth; localization to the CNS; or widespread dissemination.

Asymptomatic infants are not routinely screened for congenital infection however they may be tested for specific pathogens based on their clinical presentation (de Jong et al., 2013). Indiscriminate screening for congenital infection by measuring TORCH titres is expensive and has a poor diagnostic yield although the identification of IgM antibodies is suggestive of infection in the newborn (Khan and Kazzi, 2000). Laboratory abnormalities such as thrombocytopenia, anaemia, elevated transaminases, and elevated serum direct and indirect bilirubin levels can be seen in congenital CMV infection. The

diagnosis of congenital CMV infection is established by isolating the virus from urine or saliva and the culture will frequently become positive after one to three days of incubation (Demmler, 1991).

Treatment of newborns with asymptomatic infection is not recommended. The use of ganciclovir to treat symptomatic CMV disease should only be considered in carefully selected cases.

Antibiotic principles

Because the brain is particularly sensitive to damage caused by inflammation, the limited immunologic responses that result from antigenic challenge is known as immunologic privilege (Nigam and Lesniak, 2014). The CNS vasculature is responsible for preventing ions and solutes from entering the brain parenchyma and for enhancing regional cerebral blood flow when needed (Nigam and Lesniak, 2014). The blood–brain barrier (BBB) consists of endothelial cells which comprise the walls of the microvasculature, pericytes, and astrocytes. The tight junctions between endothelial cells inhibit the diffusion of hydrophilic molecules into the brain. In the presence of a CNS infection, WBC will migrate across the inflamed BBB through endothelial cells by diapedesis while leaving the tight junctions intact (Engelhardt and Wolburg, 2004).

Antibiotic penetration into the CNS is variable depending on which antimicrobial agent is selected to treat the infection and to what extent the cerebral meninges are inflamed. The compromise of the BBB that occurs in the face of infection will often allow hydrophilic antibiotics to enter into the CNS and the CSF. Lipophilic drugs such as vancomycin and the fluoroquinolones cross the BBB very well. Aminoglycosides and β-lactam antibiotics do not cross the BBB easily because they are hydrophilic compounds (Kim and Hall, 2014). Antibiotics are categorized as bacteriostatic or bactericidal. The bacteriostatic antimicrobial agents require an intact immune system to kill bacteria.

The administration of intraventricular or intrathecal antibiotics usually requires the presence of an external ventricular drain or a lumbar drain, respectively, to assure adequate delivery into the CSF. Intraventricular antibiotics have been recommended for the treatment of ventriculitis and for surgical prophylaxis at the time a paediatric shunt is placed (Gruber et al., 2009). Antibiotics that are considered epileptogenic, such as the beta-lactams, should not be administered intraventricularly despite their poor penetration of the BBB.

The widespread indiscriminate use of some antibiotics has resulted in the emergence of organisms that are resistant to those agents at an alarming rate with methicillin-resistant *Staphylococcus aureus* (MRSA) being one of the more concerning bacterial strains. Vancomycin was developed to guard against the development of bacterial resistance, yet new resistant bacterial strains are emerging such as vancomycin-resistant enterococci (VRE) and vancomycin-resistant *S. aureus* (VRSA). Those bacteria that are resistant to vancomycin are now treated with linezolid, until resistance to this agent emerges. The use of handwashing and alcohol-based hand sanitizers reduce the prevalence of antibiotic-resistant bacterial strains such as MRSA in the hospital setting (Kim and Hall, 2014). In surgical cases where MRSA infection is likely, vancomycin may be a better preoperative prophylactic antibiotic than cefazolin.

Perioperative infection control

There are two specific areas where direct intervention can lead to the prevention of a postoperative neurosurgical infection that include preoperative antibiotic administration and the maintenance of a sterile surgical field. The timing of preoperative parenteral antibiotic administration is important to prevent surgical site infections (SSIs). In general, intravenous antibiotics should be administered before the surgical incision is made to assure that a bactericidal concentration of the antibiotic is present in the tissue when the skin is incised (Hall, 2015). For an antibiotic to prevent the development of an infection, the drug must be present in the tissue before the bacteria gain access to that same tissue (Kainth et al., 2014). There is no evidence that antibiotics should be continued for an extended period after surgery is concluded and extending the duration of treatment beyond 24 hours should be discouraged to prevent the development of resistant organisms. In addition, there is no evidence to support the administration of multiple doses of antibiotics versus one single dose of antibiotics for neurosurgical prophylaxis (Kainth et al., 2014). The North American Spine Society developed an evidence-based guideline for prophylactic antibiotics in complex spine surgery that called for the administration of a single dose of a broad-spectrum antibiotic that covered Gram-positive organisms and was given before the skin was incised and allowed time for adequate tissue levels of the drug to be reached (Kainth et al., 2014; Hall, 2015). Allowance was made for re-dosing the antibiotics if the surgical case was lengthy or if it was associated with significant blood loss. The continued administration of antibiotics after completion of the operative case can lead to urinary tract and gastrointestinal infections such as *Clostridium difficile* colitis due to the suppression of the normal host flora (Hall, 2015). Antibiotics that are used to treat resistant organisms should not be used for surgical prophylaxis in order to prevent the further propagation of antibiotic-resistant organisms. The antibiotic selected for prophylaxis should be effective against those organisms that are most likely to cause an infection at the parent institution.

Although parenteral antibiotic administration is the primary therapeutic modality used for neurosurgical prophylaxis, the topical administration of antibiotics has become an accepted common practice particularly when a foreign body is being implanted. Antibiotic solutions such as Bacitracin have long been used to irrigate wounds prior to surgical closure. The drug selected for the irrigation fluid should be bactericidal for the local institutional flora and should possess minimal potential toxic side effects (Kainth et al., 2014). In preparing the skin for a clean neurosurgical procedure there are several issues that must be considered. The question of whether it is necessary to remove scalp hair has been a topic of great debate. In a large Cochrane database review of 11 randomized controlled trials that included more than 5000 patients, the question of whether or not preoperative hair removal from any part of the body reduced the incidence of SSI was analysed (Tanner et al., 2008). Three independent reviewers concluded that there was no evidence that the incidence of SSI was influenced by the presence or absence of hair. However, it was found that the SSI rate was higher if a razor was used to shave the hair compared to an electric clipper or depilatory creams (Hall, 2012a).

In the face of placing an indwelling permanent foreign body such as a ventriculoperitoneal shunt, many neurosurgeons will opt to clip the hair in the hope of preventing a future shunt infection that would lead to the removal of the device even though the literature does not support hair removal in either the paediatric or adult populations (Hall, 2012a). Maintaining a patient's hair, particularly when removing a benign tumour such as a meningioma, will enhance patient satisfaction without increasing their risk for a postoperative infection.

Additional measures are necessary to assure the sterility of the skin prior to making the skin incision. In one report where the postoperative neurosurgical infection rate was 0.8% in 2111 cases, the surgical scrub included three components. Betadine surgical scrub (Purdue Pharma, Stamford, CT) was initially used to expose any bacteria located deep within the hair follicles to antimicrobial agents. Alcohol solution was next used to remove the foam associated with the preliminary scrub. Lastly, DuraPrep (3M, St. Paul, Minnesota) or ChloraPrep (CareFusion, San Diego, CA) surgical solutions were applied and allowed to dry on the surgical site before draping. In the event that the hair was not removed, DuraPrep and ChloraPrep should not be used as part of the surgical prep because the hair and the surgical site must be completely dry before beginning surgery to avoid the potential for an intraoperative fire, which can add a substantial delay to the start of the procedure.

Disinfection and sterilization of surgical instruments is essential to prevent the transmission of infectious pathogens to patients having neurosurgery. Failure to comply with established guidelines for disinfection and sterilization has led to previous outbreaks of infection. The instruments used for patient care are placed in three categories, critical, semicritical, and non-critical, based on the degree of the risk of infection that is associated with the use of those instruments (Rutala and Weber, 2004). Critical items such as the surgical instruments used to perform neurosurgery have a high risk of causing infections if they are contaminated with any microorganisms. Sterilization of critical items is essential because any contamination by antimicrobial agents will most likely result in the development of first a localized and then a potentially widespread serious infection. The critical items used in neurosurgery should be purchased sterile or steam sterilized if possible. If the critical item is heat sensitive then it should be treated with ethylene oxide, hydrogen peroxide gas plasma, or with liquid chemical sterilants (Rutala and Weber, 2004). Chemical sterilants that are used in surgery include 2.4% or over glutaraldehyde-based formulations, 1.12% glutaraldehyde with 1.93% phenol/phenate, 7.5% stabilized hydrogen peroxide, 7.35% hydrogen peroxide with 0.23% peracetic acid, 0.2% or over peracetic acid, and 1.0% hydrogen peroxide with 0.08% peracetic acid (Rutala and Weber, 2004). The exposure time for these chemical sterilants is from 3 to 12 hours except for 0.2% or over peracetic acid where the sporicidal time is 12 minutes at 50–56°C (Rutala and Weber, 2004). Instruments should be cleaned to remove any organic or inorganic material before they are either steam or chemically sterilized. Some limitations to liquid chemical sterilants include the inability to wrap sterilely the surgical instrument after it is processed which means that maintaining sterility during storage is impossible and instruments exposed to chemical sterilants should be rinsed afterwards with water which is generally not sterile (Rutala and Weber, 2004).

Prion disease

Prion disease or transmissible spongiform encephalopathy is caused by the abnormal deposition of the insoluble isoform of a cellular protein PrP^c in the CNS (Domachowske et al., 2014). There are three forms of the disease: (1) sporadic; (2) familial; and (3) iatrogenic, following exposure to the protein (Belay, 1999). The TSEs that are considered familial include familial Creutzfeldt–Jakob disease (CJD), Gersmann–Sträussler–Scheinker disease, and fatal familial insomnia (Belay, 1999). A newly recognized variant form of CJD (vCJD) was reported in young people in the United Kingdom in 1996 (Belay, 1999). Transmission of bovine spongiform encephalopathy from cows to humans is now known to be the cause of vCJD. Exposure to the protein has resulted when patients received human growth hormone prepared from human cadavers, dural grafts, corneal transplants, and exposure to contaminated neurosurgical instrumentation (Domachowske et al., 2014). Definitive diagnosis usually requires a brain biopsy with histopathological examination, immunocytochemical staining, and Western blotting to detect the PrP^c protein (Budka et al., 1995).

There are strict decontamination procedures for the neurosurgical instruments that are used in performing a brain biopsy in the patient suspected of having Creutzfeldt–Jakob disease (CJD) in order to prevent transmission of the infectious agent to other individuals having neurosurgery with the same instruments. When performing a brain biopsy in a standard operating room, cover work surfaces with disposable material that can be removed and incinerated after the procedure is completed. Ideally, the best way to ensure that there is no risk of infectivity of contaminated instruments is to discard and then destroy them by incineration (WHO, 1999). If the surgical facility has the ability to quarantine instruments until the diagnosis is confirmed than that is an acceptable alternative to the needless destruction of expensive instruments in suspected cases. If destruction of the surgical instrumentation is impractical, then they should be handled in the following manner: (1) keep the instruments moist until they are decontaminated; (2) clean instruments as soon as possible after use; (3) do not mix contaminated with non-contaminated instruments; and (4) proceed with the recommended method of decontamination (WHO, 1999).

The decontamination process for the durable instrumentation used during surgery is justifiably very involved. Two or more methods of decontamination should be combined when sterilizing against these agents. An example is the use of both heat and sodium hydroxide (NaOH) either simultaneously or consecutively. Hot alkaline hydrolysis both cleans and inactivates macromolecules. Liquids that are used for cleaning contaminated instrumentation should be decontaminated *in situ* by the addition of NaOH or sodium hypochlorite and then disposed of as routine hospital waste. Absorbent material that is used to soak up liquid spills of contaminated cleaning fluid should be incinerated after use. The recommended decontamination methods for cleaning contaminated heat-resistant instruments in the order of preference are listed in **Box 97.1**.

Controversies

Several controversial issues exist in neurological surgery that pertain to the prevention and management of CNS infections. A recent

Box 97.1 Decontamination methods for cleaning heat-resistant instruments used in performing a brain biopsy for Creutzfeldt–Jakob disease

1. Immerse in 1 Normal (N) NaOH and heat in a gravity displacement autoclave for 30 minutes at 121 degrees centigrade (°C). Clean and rinse in water before routine sterilization.
2. Immerse in 1N NaOH or sodium hypochlorite at a concentration of 20 000 ppm available chlorine for 1 hour. Transfer to water and heat in a gravity displacement autoclave for 1 hour at 121°C prior to cleaning and routine sterilization.
3. Immerse in 1N NaOH or sodium hypochlorite for 1 hour then remove and rinse in water. Transfer to an open pan and heat for 1 hour in a gravity displacement (121°C) or porous load (134°C) autoclave before cleaning and routine sterilization.
4. Immerse in 1N NaOH and boil for 10 minutes at atmospheric pressure. Clean and rinse in water before routine sterilization.
5. Immerse in sodium hypochlorite (preferred) or NaOH (alternative) at ambient temperature for 1 hour. Clean and rinse in water before routine sterilization.
6. Autoclave at 134°C for 18 minutes (WHO, 1999).

and somewhat controversial practice that has come under some scrutiny is the application of intrasite vancomycin powder (VP) to prevent SSI most notably in complex spine surgery. The rationale for using VP is to achieve high local concentrations of the drug at the location where an infection would be most likely to develop with a minimal amount of systemic redistribution. This non-Food and Drug Administration off-label use of VP has been analysed through systemic reviews and meta-analyses. A recent review of the clinical evidence for the use of in-the-wound VP to prevent infection in spinal surgery found that the odds of developing a deep infection in patients that received VP was 0.23 times the odds of experiencing an infection without VP (Bakhsheshian et al., 2014). It was estimated that VP could save up to $220 000 to $500 000 per 100 patients undergoing complex spinal surgery. Potential disadvantages to the use of VP were an increase in vancomycin resistance, an increase in hardware infections due to bacteria not covered by vancomycin, systemic side effects from the vancomycin such as hypotension, colitis, skin flushing known as red man syndrome, and Stevens-Johnson syndrome, and whether there is any influence of the drug on spinal fusion rates. The appropriate dosage of topical VP in children and adults is unknown.

Cranial infections

Thangaraj Munusamy, Boon Hoe Tan, and Eugene Yang

Introduction

Cranial infections continue to be an important cause of mortality and morbidity worldwide. To understand cranial infections, knowledge of anatomy is important because it relates to both pathogenesis, complications, and functional sequelae. Microorganisms, owing to their intrinsic properties and distinct characteristics, produce relatively specific clinical syndromes in cranial infections. Definitive treatment depends on prompt microbial identification and antimicrobial treatment, reduction of microbial load, relief of excessive pressure or mass effect and modulation of the host's immune response to allow successful microbial clearance while minimizing inflammation and oedema. In this chapter, we will discuss the management of common cranial infections and their associated clinical conundrums from a neurosurgical perspective.

Brain abscess

Brain abscess is defined as a focal intracranial infection that starts as a focus of cerebritis that gradually progresses into a collection of pus with capsular formation. Brain abscesses can arise from three principal sources:

1. Direct extension of an adjacent source of infection
2. Hematogenous spread from a distant source
3. Direct inoculation into brain through a dural breach

Examples of direct extension from adjacent sources include brain abscess secondary to suppurative otitis media, mastoiditis, or anteriorly through the paranasal sinuses. These direct extensions usually affect either the temporal lobes, cerebellum, or the frontal lobes or the sellar and parasellar regions. Hematogenous spread from a distant source include septic emboli showers from infective endocarditis, as well as distant sources of infection such as an intraabdominal collection or osteomyelitis. The body's natural protective mechanism is to filter these pathogens through the capillary circulation of the lungs and in the presence of AV shunts these protective mechanisms can be bypassed, for example, congenital cyanotic heart disease or pulmonary arteriovenous malformation such as in Osler-Weber-Rendu disease (Helweg-Larsen et al., 2012; Chenran et al., 2014; Yakut et al., 2015).

Brain abscess is more commonly reported in immunocompromised patients: patients who are HIV positive, receiving chemotherapy for treatment of malignancy, receiving steroids, or immunosuppressive treatment for underlying organ transplantation or inflammatory disorders.

Direct breach of dura can form a direct portal for migration of bacteria into the intracranial cavity usually as a result of trauma, for example, depressed skull fractures and inoculation of foreign body, or as a result of neurosurgical procedures. Abscess following neurosurgery may result from the nature of the surgical procedure itself such as in implant surgery (electrodes, shunts), external ventricular drains, intracranial pressure monitors, or insertion of gliadel wafers in glioma surgery (McGovern et al., 2003).

Stages of infection

Four pathological stages of cerebral abscess formation are recognized:

1. Early cerebritis
2. Late cerebritis
3. Early capsule formation
4. Late capsule formation

The early stages of abscess formation are characterized by early cerebritis (day 1–3), which involves tissue necrosis, accumulation of neutrophils, and onset of oedema. From day 4–9, the earlier neutrophilic infiltrate progresses into a predominantly macrophage and lymphocytic infiltrate. Early capsule formation starts at day 10–13, which is thinner on ventricular side. This may lead to abscess rupture into ventricular cavity leading to ventriculitis. Late capsule formation starts after day 14, and characterized by formation of gliosis, collagenous, and granulation layers (Erdogan and Cansever, 2008).

Pathogens

The commonest organisms to cause cerebral abscess are streptococci, particularly *strep. Milleri* group, followed by anaerobic bacteria, staphylococci, and Gram-negative bacteria. Enteric Gram-negative organisms such as pseudomonas, proteus, and *E. coli* usually result from extension from otogenic or paranasal sinus foci, systemic bacteraemia, or in immunocompromised patients. Streptococci

account about 54% of cases, *Staphylococci* 15%, Gram-negative bacteria 8%, anaerobic bacteria 17%, and nocardia 2% (Helweg-Larsen et al., 2012; Chenran et al., 2014; Yakut et al., 2015).

Organism such as *Listeria monocytogenes*, and *Nocardia* should be considered in immunocompromised states such as HIV patients, patients with malignancy, transplant recipients, patient whom are on treatment with chemotherapy, or patient whom are on long-term steroid exposure.

Mortality from *Nocardia* brain abscesses is significant, with rates of 31–77% and treatment is usually with trimethoprim-sulfamethoxazole regime for a prolonged period (3 to 12 months) (Weerakkody et al., 2015).

The finding of a tuberculous brain abscess requires investigation to rule out underlying HIV exposure. Diagnostic criteria as described in 1978 by Whitener are: 1. Macroscopic evidence of true abscess formation within the brain substance (at surgery or biopsy) 2. Histological confirmation that inflammation in the abscess was composed predominantly of vascular granulation tissue containing acute and chronic inflammatory cells. 3. Positive pus culture or evidence of acid-fast bacilli. Female patients tend to be more afflicted compared to males with a mean age of 23.9 years. Incidence of tuberculous brain abscess is 4–8% of CNS tuberculosis in the absence of HIV infection (Mohindra et al., 2016).

Tuberculoma presents a diagnostic challenge, its appearance on conventional CT and MR imaging mimics multiple other entities including metastatic brain tumours, neurocysticercosis, toxoplasmosis and fungal brain abscess (**Fig. 98.1**). They are firm, avascular, spherical masses that range from 2 to 10 cm in diameter, well-circumscribed, and contain areas of caseating necrosis with tubercle bacilli. CSF evaluation in isolated tuberculoma is generally non-specific. Management is usually with medical therapy. The indication for surgery is limited as most tuberculoma responds well with adequate antibiotic treatment and steroids. Occasionally, surgical treatment is warranted to establish diagnostic certainty or to relieve significant mass effect and underlying brain compression (Chatterjee, 2011; Monteiro et al., 2013).

With the widening therapeutic use of immunosuppressive treatments (steroids, immunomodulators chemotherapy), increasing prevalence of HIV and AIDS, and organ transplant recipients, fungal infections are becoming increasingly frequent. Commonly reported organisms include CNS aspergillosis, Scedosporium, Cryptococcus neoformans and endemic mycoses (Vergara et al., 2015). Fungal brain abscess has a high mortality rate especially in immunocompromised patients.

Clinical findings

The most common symptoms are fever (60%), neck stiffness (25%), nausea or vomiting (40%), focal neurological deficits (57%), seizures (21%), and impaired consciousness (45%) (Helweg-Larsen et al., 2012). The classical triad of headache, fever, and nausea or vomiting is only present in one in five cases. The triad of headache, fever with focal neurological deficits is only seen in one in four cases.

Headaches, change in mental status with confusion and drowsiness, accompanied with symptoms of nausea and vomiting may represent the presence of increased intracranial pressure from the mass effect large abscess collection or collections and perilesional oedema.

Neck stiffness or nuchal rigidity may occur in setting of abscess rupture into the ventricular cavity leading to ventriculitis and meningitis.

Focal neurological deficits are dependent on the location of an intracranial abscess, with resultant loss of function in the corresponding location of the brain. This may manifest as hemiparesis, personality change, visual field deficits, aphasia, nystagmus, and ataxia.

Radiological features

Magnetic resonance imaging provides both diagnostic accuracy and sensitivity and is considered the diagnostic neuroimaging of choice for investigation and workup of newly diagnosed brain abscess. Classically described as a ring-enhancing lesion on contrast-enhanced T1-weighted image. MRI also provides additional information such as the surrounding enhancing rim, and degree and extent of perilesional oedema that typically occurs with abscesses (**Fig. 98.2**).

In the cerebritis stage, pyogenic brain abscesses are T1 hypointense and T2 hyperintense with minimal or non-homogenous enhancement. Tuberculous cerebritis is seen as an ill-defined, hypoattenuated

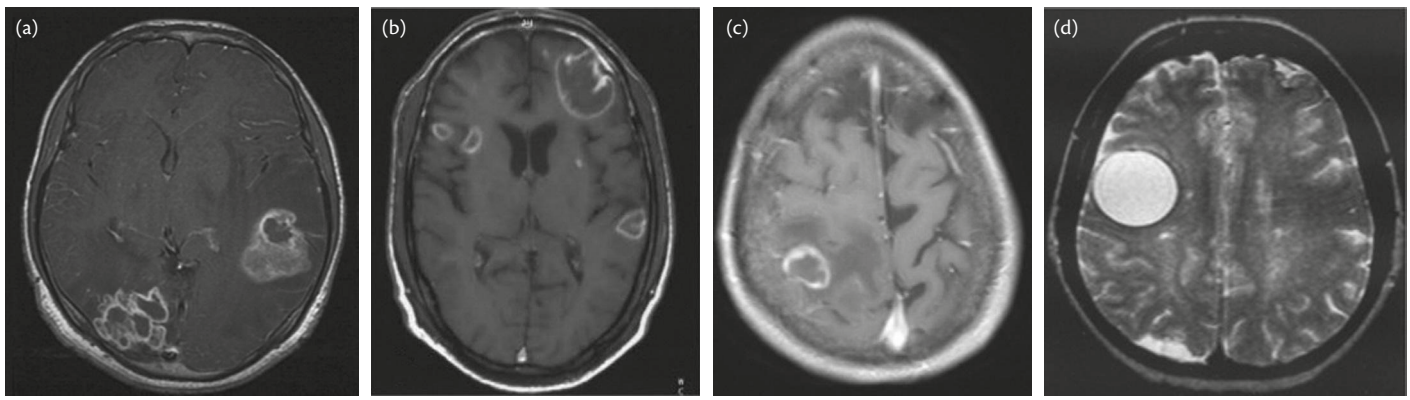

Fig. 98.1 MR imaging of CNS infections. (A) Cerebral tuberculoma (Helmy et al., 2011); (B) cerebral toxoplasmosis (Batra et al., 2004); (C) fungal brain abscess (Bagla et al., 2016); (D) cerebral hydatid cyst (Seckin et al., 2008).

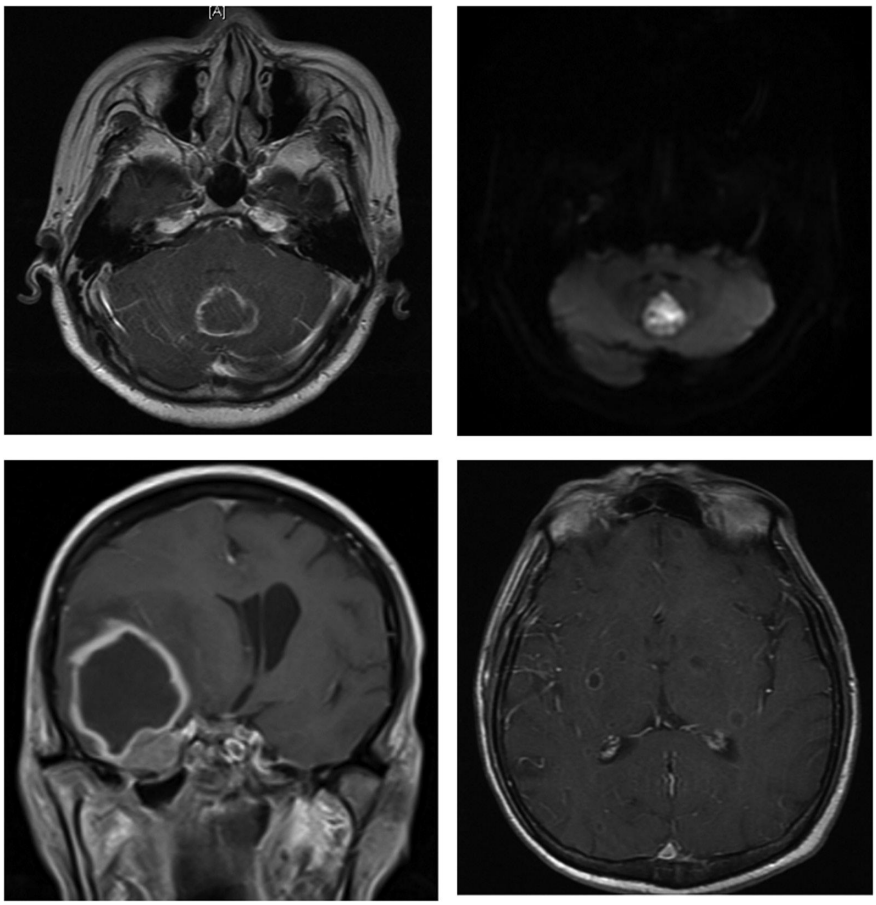

Fig. 98.2 MR imaging of pyogenic brain abscesses. (A and B) (Top row): cerebellar abscess appearing as a ring-enhancing lesion on contrast-enhanced T1-weighted image (A) and hyperintense on DWI (B). (C) (Bottom left): right temporal abscess in a patient with advanced nasopharyngeal carcinoma treated with radiotherapy. (D) (Bottom right): multiple abscesses in a patient with infective endocarditis.

areas of gyral enhancement. Fungal cerebritis is usually non-enhancing and located in the basal ganglia or deep white matter. All mature pyogenic, tubercular, and fungal abscesses demonstrate hypointensity on T1 imaging, hyperintensity on T2 imaging, and demonstrate good rim enhancement on contrast sequences. Most pyogenic and tubercular abscesses show a smooth or lobulated outer-wall. About half of fungal abscess have a creanated wall. Fungal abscesses also show intracavitary projections directed centrally from the wall without any contrast enhancement, this is not seen in other type of abscess on conventional MRI (Cartes-Zumelzu et al., 2004; Luthra et al., 2007). In immunocompromised patients, there may be relative lack of contrast enhancement which can confound diagnosis. There is a case report from 2004 of an immunocompromised patient post bone marrow transplantation which reported minimal enhancement despite fulminant cerebral toxoplasmosis (Ionita et al., 2004).

Areas of restricted diffusion are seen in pyogenic abscesses on diffusion-weighted imaging sequences (Fig. 98.2). Necrotic material is present within the abscess cavity which contains inflammatory cells, bacteria, and pus which restricts water-motion. MRI Imaging of pyogenic and tubercular abscesses will show increase signal in diffusion-weighted imaging (DWI) imaging with low apparent diffusion coefficient (ADC) values within the core of the cavity. In contrast, DWI and ADC in fungal abscess shows restricted diffusion in the projections and wall but not in the core of the abscess.

There is also some evidence to suggest the use of DWI to monitor response to medical therapy. DWI signals change from initial high signal intensity to low signal intensity, which suggest the disappearance of purulent content within the abscess core, indicating a good therapeutic response.

MR spectroscopy (MRS) in brain abscesses shows metabolites associated with hypoxia and cellular breakdown such as amino acids, lipid, lactate, acetate, and succinate in differing amounts between the various abscesses, and may help in distinguishing the subtypes of abscess (Cartes-Zumelzu et al., 2004; Luthra et al., 2007).

CT imaging with IV contrast enhancement typically reveals an area of low-density centre with rim enhancement peripherally.

MRI or CT also enables stereotactic guided abscess aspiration to facilitate microbiological diagnosis and decrease bacterial load.

Management

A multidisciplinary approach for management and treatment of cerebral abscess is required, involving a neurosurgeon, a neuroradiologist, and an infection disease specialist. The key principles to

consider is determining a microbiological diagnosis (from the abscess itself or from a potential source).

Although there is no absolute size threshold that necessitates surgical intervention, abscesses more than 2.5 cm in maximum dimension should ideally be treated surgical either through craniotomy and formal excision of the entire abscess cavity, or through needle aspiration of the abscess usually performed under stereotactic guidance. Excising abscesses in their entirety can improve radiological appearances but with additional risk, particularly of postoperative seizure. Smaller abscess can simply be needle aspirated under image guidance (Radoi et al., 2013).

Whenever an intracranial abscess is identified, the ultimate source and repository of infection must be removed to prevent recurrence. Resection of otomastoiditis, drainage of suppurative otitis media or sinus infection, drainage of distant sources of infection such as intra-abdominal collections, wound debridement of infected wound should all be considered concurrently with abscess treatment. Occasionally post-traumatic abscess may contain foreign materials such as bone chips, gun-shot pellets, bullets, or stones, and, if safe to do so, these should be removed to reduce recurrence risk.

Stereotactic aspiration of abscess has the advantage that it is simple, with less potential morbidity than craniotomy, however it is associated with increased risk of recurrences. Craniotomy and excision of the abscess has a lower incidence of recurrence, and is particularly indicated if there is a significant mass effect, if there are difficulties in the diagnosis, if the abscess is due to trauma with introduction of foreign materials, or in the posterior fossa (Ratnaike et al., 2011; Helweg-Larsen et al., 2012; Radoi et al., 2013; Aras et al., 2016).

The abscess capsule provides a physical barrier to entry of antibiotics into the abscess cavity mitigating their effectiveness, furthermore the acidic abscess environment may also inhibit the effectiveness of antibiotics.

Abscess material should be sent for microscopy and extended culture to enable identification of the offending organism. Aspiration of abscess will thus facilitate commencement of targeted antibiotic therapy based on culture sensitivity results. Commencement of empirical antibiotic therapy is dependent on several factors including—suspected bacterial involvement based on history and examination, preliminary results of Gram stain, and patterns of microbiology of the local setting.

Choice of antibiotics should take into account of the suspected source of abscess (i.e. sinusitis vs. otogenic vs. post-traumatic), pharmacokinetics of CSF penetration, duration, and route of administration (i.e. intravenous vs. intraventricular). Common empirical antibiotic regimes include use of third-generation cephalosporins with metronidazole for additional anaerobic cover especially in cases of direct adjacent source of infection (i.e. sinusitis, otogenic). In cases where there is direct inoculation such as post-trauma or post brain surgery, a combination of third-generation cephalosporins with additional Gram-positive coverage with vancomycin can be considered. Duration of antibiotic therapy is typically for 6 to 8 weeks, usually given intravenously at high dose to facilitate blood brain barrier penetration. Monitoring of treatment response requires both neuroimaging and biochemical (such as plasma C-reactive protein) markers allowing titration of antibiotic therapy duration (Cartes-Zumelzu et al., 2004; Luthra et al., 2007).

Fungal brain abscess is treated with antifungal drugs, for example, voriconazole for aspergillus infection and amphotericin B for candida and mucormycosis. External ventriculostomy may be used to deliver intrathecal antifungal drugs, however this practice is not universally accepted. Fungal brain abscess is associated with significant mortality especially in immunocompromised patients (Grannan et al., 2014; Ma et al., 2015; Gavito-Higuera et al., 2016; Patterson et al., 2016).

Corticosteroid use in brain abscess is controversial, it can reduce brain swelling with improvement of mass effect and impending herniation. However, it can also lead to a decreased host immune response to infection, and may ameliorate formation of the abscess wall leading to more destruction of perilesional viable brain tissue, and delayed containment of the abscess. Steroid treatment prior to surgery does not appear to significantly change outcome: in a retrospective study 21% treated patients versus 23% non-treated patients had GOS less than 3 at discharge (Helweg-Larsen et al., 2012). Functional outcome in patients who received steroids after surgery was also not significant with a GOS less than 3 in 25% on steroids versus 20% without steroids (Helweg-Larsen et al., 2012). In an alternative case series, use of steroids was associated with higher mortality compared to non-steroid group (15.6% vs. 3.9%) (Ratnaike et al., 2011; Radoi et al., 2013; Aras et al., 2016).

A combination of surgical and medical treatments is advocated for the management of cerebral abscess. However, this also needs to take into account of the overall picture of the patient, that is, patient factors (perioperative anaesthetic, cardiac, and respiratory risks) and pathological factors (size, number, and location of abscesses).

Neurocysticercosis and echinococcosis

Neurocysticercosis is the most common parasitic infection of the brain worldwide, with the second being echinococcosis (hydatid cyst disease). Neurocysticercosis is caused by the encysted larval stage of the tapeworm *Taenia solium*. They can present either in the parenchymal form or extraparenchymal form. The parenchymal form is the most common and usually involves the grey/white matter junction, with a more favourable prognosis compared to extraparenchymal. The extraparenchymal form shows a wider range of locations throughout the CNS and is associated with higher parasitic burden load and poorer prognosis. It can lead to arachnoiditis, inflamed meninges, entrapment of cranial nerves, and blockage of CSF flow with resultant hydrocephalus. An absolute diagnosis of neurocysticercosis if often challenging as surgery is not indicated in most cases which thereby precludes histological identification of parasites. Comprehensive neuroimaging criteria have been introduced to improve degree of diagnostic certainty (**Fig. 98.3**). Treatment consists of antihelminthic drugs such as albendazole and praziquantel, antiepileptics, and steroids to dampen down the inflammatory process. Surgery may consist of cyst extirpation or insertion of CSF diversion devices for treatment of hydrocephalus (Baird et al., 2013; Del Brutto et al., 2017; Gripper and Welburn, 2017).

Cerebral hydatid disease is a rare parasitic infestation caused by the larvae of Echinococcus tapeworm. It is endemic in the Middle East, the Mediterranean, Africa, India, Australia, and parts of South America. Intracranial echinococcosis could present either in the cystic form (*E. granulosus*) or the alveolar form (*E. multilocularis*). It most frequently occurs in the supratentorial region, mainly in the vascular territory of the middle cerebral artery. Symptoms are related

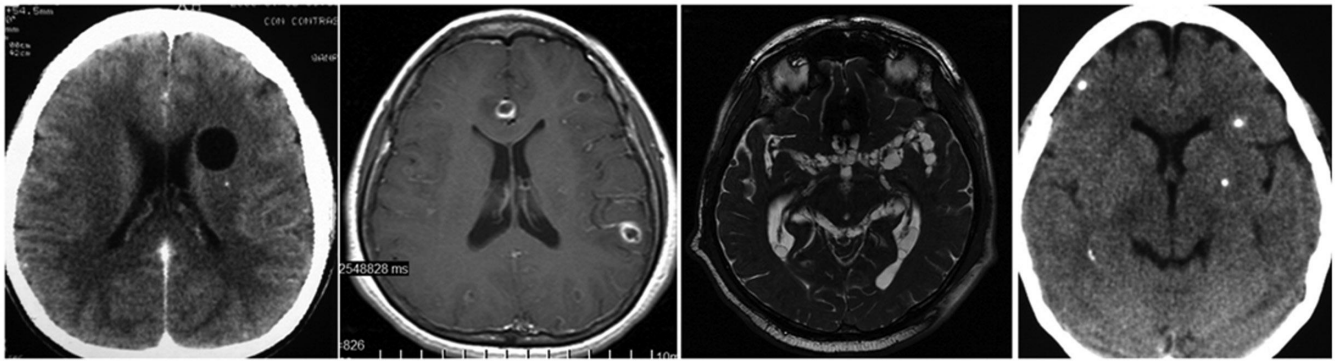

Fig. 98.3 Major neuroimaging criteria for neurocysticercosis (Del Brutto et al., 2017). Cystic lesion without discernible scolex (A), ring-enhancing lesions (B), multilobulated cysts in basal subarachnoid cisterns, (C) and typical parenchymal brain calcifications (D).

to local mass effect due to the location of the cyst or raised intracranial pressure. Computed tomography and magnetic resonance imaging are reliable diagnostic tools. Radiologically the cyst appears spherical and well-circumscribed with no enhancement, calcification, or perilesional oedema (Fig. 98.1). The alveolar form shows a well-defined multiseptated mass consisting of solid and cystic components with calcification in the solid portion. Cystic fluid is isodense or isointense with CSF. The cyst is usually solitary, although multilocular and multiple cysts in the brain have been reported. Extracranial disease is frequently absent in solitary cerebral hydatid cyst; however, it is mandatory to screen the rest of the body. Differential diagnoses include arachnoid cyst, epidermoid cyst, neurenteric cyst, cystic primary brain tumour or metastases, and brain abscess.

Surgical excision of the cyst using Dowling's method has been classically described: a wide scalp flap and dissection of the atrophic cortex, lowering the head of the operating table to benefit from gravity and the use of warm saline between the hydatid cyst and brain parenchyma to deliver the cyst. Inadvertent rupture of the cyst during manipulation may lead to spread of the parasite and anaphylactic shock (Bukte et al., 2004; Luo et al., 2013; Ulutas et al., 2015).

Extradural and subdural collection

An empyema is a collection of pus within a normal anatomical space therefore a collection in the subdural space is deemed an empyema, while a collection in the extradural space, which is only a potential space, is designated an abscess. Extradural abscesses are often located in the frontal region and are limited by sutures. Patients with extradural abscess may have subtle clinical signs and neurological deficits only occur when there is sufficient mass effect caused by the collection. If the dura mater is breached or with spread via dural venous anastomoses, empyema can progress into the subdural space or cause thrombophlebitis and cerebritis. Subdural empyema is associated with a high morbidity and mortality. As well as extension from extradural empyema it can occur secondary to haematogenous spread or as a postoperative complication.

Subdural empyema

Subdural empyema is a neurosurgical emergency associated with mortality rate of up to 20% and morbidity rate of 50% despite intervention (Le Beau et al., 1973; Nathoo et al., 1999). In immunocompetent patients, it occurs most commonly in the second decade of life and there is a marked male predominance with a male-to-female ratio of 3:1 (Osborn and Steinberg, 2007). Outcome depends on factors such as age, comorbidities, primary organism, and prompt diagnosis and treatment. Subdural empyema has the propensity to spread rapidly due to lack of fibrin capsule and anatomical barriers in the subdural space. The most common sources of infection are from otitis media and infection of the paranasal or mastoid air sinuses. Other causes include direct spread from meningitis, haematogenous spread from distant sites, surgical site infection and head trauma with skull fracture and dural tear (Munusamy and Dinesh, 2015). Concomitant intraparenchymal abscess may occur in 6–22% of cases and epidural abscess in 9–17% (Osborn and Steinberg, 2007).

Clinical presentation

Patients with subdural empyema typically present with fever, headache, and altered mental state followed by rapid neurological deterioration. The median time from the onset of symptoms to diagnosis is two days (French et al., 2014). Seizures are common and occur in up to 63% of patients (Cowie and Williams, 1983). Other presenting symptoms will depend on underlying aetiology for example sinusitis, mastoiditis, otitis media, meningitis, postoperative wound infection, systemic infection, or head trauma. Progression into an expanding mass lesion results in signs and symptoms of raised intracranial pressure. Cerebral oedema and hydrocephalus may occur secondary to disruption of cerebral blood flow or CSF flow. Thrombosis of the cortical veins or dural venous sinuses from direct spread or septic emboli result in venous hypertension and may progress to cerebral infarction.

Pathogenesis

The pathogenesis of subdural empyema is similar to that of brain abscess. The causative microorganisms vary according to the primary source of infection. They are often monomicrobial, however polymicrobial infections are not uncommon especially if the source of infection is from the paranasal sinuses (Nathoo et al., 1999). Aerobic and microaerophilic *Streptococci* are usually implicated

in subdural empyema secondary to mastoiditis or sinusitis (Miller et al., 1987). In postoperative and post-traumatic subdural empyema, *Staphylococcus aureus* is commonly isolated whereas in the immunocompromised, *Klebsiella pneumonia* is often the culprit (Greenlee et al., 2003). Other causative microorganisms that have been reported include *Escherichia coli* and *Salmonella* species (Munusamy and Dinesh, 2015). Microbiological diagnosis of subdural empyema is based on positive culture of pus or infected material taken during surgical drainage or samples taken from the primary source or infection. The success rate for culturing bacteria from surgically evacuated subdural pus ranges from 54% to 81% (Mauser et al., 1987; Nathoo et al., 1999). Low culture positivity can be explained by the use of broad-spectrum antibiotics as empirical treatment for infection before sampling and difficulties in culturing anaerobic organisms.

Radiological features

Radiological diagnosis can be made by imaging with contrast-enhanced CT or MRI. Subdural empyema appears as a crescent-shaped collection that crosses suture lines on the surface of the brain below the cranial vault or adjacent to the falx or tentorium that typically show rim enhancement with administration of contrast media. However, occasionally contrast-enhanced CT may appear normal or show subtle brain swelling especially in chronic cases where well-organized subdural pus may fail to generate peripheral enhancement (Moseley and Kendall, 1984; Munusamy and Dinesh, 2015) (**Fig. 98.4**). In this instance, MRI is more sensitive in detecting subdural empyema particularly at the skull base, in the posterior fossa, or along the falx cerebri. Subdural empyema has high signal intensity on DWI and low signal intensity on ADC maps, similar to brain abscess and ventriculitis. Thus diffusion-weighted MR imaging can reliably distinguish subdural empyema from subdural hematoma or reactive subdural effusion that may also occur after trauma, surgery, or meningitis (Wong et al., 2004).

Treatment

The principles of treatment for subdural empyema consist of surgical evacuation of pus and bacteriological identification, eradication of the primary foci of infection and adequate antibiotic therapy (Miller et al., 1987). Surgical intervention varies between burr hole, craniotomy or craniectomy and controversy exists over the procedure that is most effective (Pathak et al., 1990). Results of all three have been shown to be comparable as long as effective drainage of purulent material and relief of mass effect was achieved (Bok and Peter, 1993). In general, if the empyema is non-viscous and there are no loculated collections, evacuation via burr holes is adequate and can avoid potential surgical complications associated with longer duration or more complex surgery. However, if the pus is thick or well organized, a craniotomy is recommended to allow adequate access and drainage (Munusamy and Dinesh, 2015) (**Fig. 98.4**). In some cases, the underlying brain may be markedly swollen necessitating craniectomy. Craniectomy should also be considered in the postoperative setting if there is intraoperative suspicion of osteomyelitis of the bone flap which may act as a devascularized nidus of ongoing infection. If the source of infection is from an otologic or extracranial focus, exploration and drainage of the primary source must be performed. Initiation of empirical antibiotic therapy without delay is recommended if the patient is septic and clinically unwell from

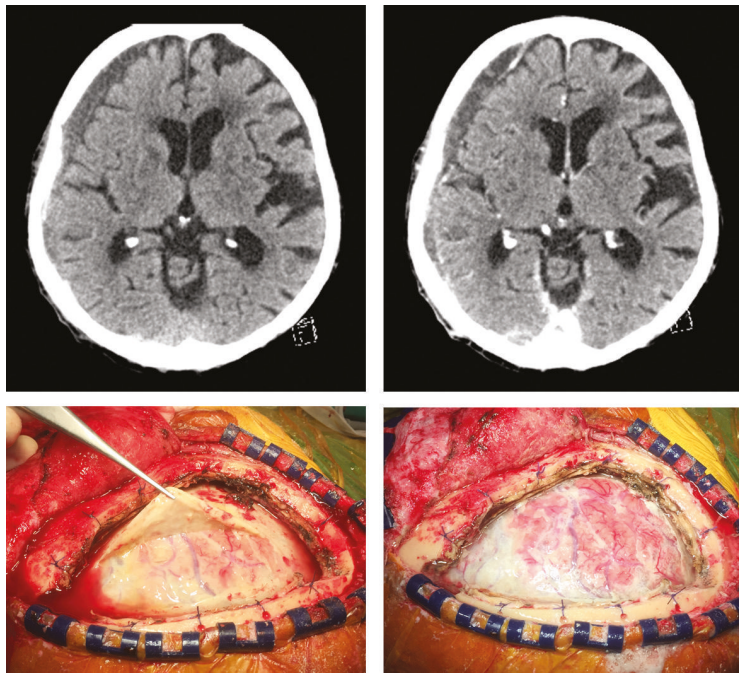

Fig. 98.4 Craniotomy and evacuation of subdural pus in a patient diagnosed with subdural empyema. (A and B) (Top row): CT scan before (A) and after (B) contrast media administration. Subtle contrast enhancement was seen in this case where the subdural pus was well organized. (C and D) (Bottom row): thick layer of subdural pus lifted off brain (C) and subdural space was irrigated with gentamicin-added saline solution. Underlying brain was hyperaemic but not swollen (D) thus bone flap was replaced, and antibiotic therapy continued.

the subdural empyema. Further antimicrobial therapy should be targeted against the causative microorganisms revealed by Gram stain or special bacterial stains, positive bacterial culture result and knowledge of the bacterial profile at the primary site of infection. Antibiotic therapy is usually continued for 4–6 weeks depending on the clinical and radiological response and expert advice from the infectious disease specialist and microbiologist should be sought at the earliest opportunity (Leys et al., 1986).

Postoperative subdural empyema has been described following craniotomy, but very rarely can be associated with burr hole drainage of chronic subdural haematoma. Presumably, the relatively simple and limited procedure minimizes tissue trauma and reduces the extent of bacterial inoculation. However, they are managed in a similar fashion where the goals of surgery are to achieve adequate decompression and evacuation of empyema. Burr holes are reopened and empyema drained however if this is insufficient conversion to craniotomy is mandatory. *Propionibacterium acnes*, a ubiquitous skin commensal can rarely be implicated with an indolent clinical presentation and course of progression (Gritchley and Strachan, 1996).

Cranial extradural abscess

Cranial extradural abscess is a suppurative infection that arises between the inner table of the skull and the dura as a result of contiguous spread from adjacent structures. It is traditionally associated with sinusitis, mastoiditis, otitis media and skull osteomyelitis (Calfee and Wispelwey, 1999). At present, the common causes are secondary to infection following neurosurgical procedures and head trauma with skull fracture and open wound. The bacteriology and pathogenesis of epidural abscess is similar to subdural empyema, but they have a sharp demarcation, slower progression rate, and an indolent course owing to the tight adherence of the dura mater to the skull. As a result it has an insidious onset and fever or headache may be the only clinical presentation. In some cases symptoms this may take weeks to develop. However, if left untreated, the infection may extend and progress to cause complications such as skull osteomyelitis, dural venous sinus thrombosis, purulent leptomeningitis, subdural empyema, and brain abscess (Pradilla et al., 2009). Contrast-enhanced CT and MRI demonstrate a lentiform-shaped enhancing lesion and a thickened dural surface that reliably distinguishes epidural abscess from sterile epidural collection. In addition, CT may also show bony destruction and fragmentation in patients with underlying skull osteomyelitis or mastoiditis. Interestingly, DWI may be an adjunct for differentiating between subdural and epidural empyemas. Subdural empyema shows high signal intensity on DWI whereas epidural empyema tends to be of low or mixed signal intensity (Tsuchiya et al., 2003). The mainstay of treatment and management of cranial epidural abscess is similar to subdural empyema. Surgical drainage of pus can be adequately performed via burr hole or craniotomy. Rarely the skull bone would need to be removed if there is severe underlying osteomyelitis (Tsai et al., 2003).

Skull osteomyelitis

Osteomyelitis of the skull usually results from spread of otogenic or odontogenic infections, head trauma with open wound or following surgical procedures involving the scalp or cranium. Patients present with fever and symptoms associated with the underlying cause. Forehead scalp swelling is seen in osteomyelitis of the frontal bone due to formation of subperiosteal abscess that was first described as Pott's puffy tumour by Sir Percivall Pott in 1760 (Kombogiorgas and Solanki, 2006). Gradenigo-Lannois syndrome is a rare complication of osteomyelitis involving the apex of the petrous temporal bone where patients present with a triad of symptoms consisting of diplopia due to abducens nerve palsy, ipsilateral periorbital or facial pain related to trigeminal nerve involvement and persistent otorrhoea associated with otitis media (Heshin-Bekenstein et al., 2014). Facial nerve or lower cranial nerves palsies may be seen in malignant otitis externa due to osteomyelitis of the skull base caused by *Pseudomonas* infection. *Aspergillus* infections have also been shown to cause skull-based osteomyelitis without any evidence of otitis externa (Pincus et al., 2009). Progression and extension of skull osteomyelitis may lead to sequelae of epidural abscess, subdural empyema, or brain abscess (Johnson and Batra, 2014). Anterior skull base osteomyelitis caused by mucormycosis is seen in many parts of the world, particularly in immunocompromised patients. The bacteriology of skull osteomyelitis depends on the site of infection and underlying cause. MRI is the diagnostic imaging modality of choice to detect changes to the diploë or cancellous bone and for detailed visualization of the skull base, cranial nerves, and soft tissues. In addition, leukocytosis and raised erythrocyte sedimentation rate (ESR) are helpful to make the diagnosis (Chang et al., 2003). Treatment of skull osteomyelitis consists of surgical debridement and biopsy or removal of infected bone flap followed by long-term antibiotic therapy directed against the responsible pathogen. Eradication of the primary source of infection is equally important to ensure successful treatment and to minimize the risk of recurrence (Pincus et al., 2009). Furthermore, there may be a role for hyperbaric oxygen therapy as an adjuvant therapy in the management of chronic refractory osteomyelitis of the skull base. Hyperbaric oxygen therapy has been suggested as an option in these cases as it enhances phagocytic oxidative killing of aerobic microorganisms and promotes angioneogenesis and osteoneogenesis (Prasad et al., 2014). Serial measurement of ESR or CRP are useful markers to monitor efficacy of treatment. Radiological follow-up with Gallium-67 bone scan can also be used to define transition from active to inactive osteomyelitis of the skull base (Chang et al., 2003). Prognosis is usually good if diagnosed and treated adequately.

Meningitis, ventriculitis, and ventriculoperitoneal shunt infections

Postoperative meningitis is a risk following neurosurgery in which the dura is breached with reported rates ranging between 0.14 to 9.2%. Patients commonly present with headache, fever, neck stiffness, change in mental status, and occasionally with nausea and vomiting. Delay in diagnosis may occur if patient symptoms such as headaches is attributed to postoperative pain, and fever symptoms are masked by the use of antipyretics. However, the clinical course of postoperative meningitis is not as fulminant as community-acquired meningitis and mortality is unusual (Srinivas et al., 2011).

Diagnosis of meningitis usually requires CSF sampling and analysis, usually via lumbar puncture. CSF examination in bacterial

meningitis reveals raised total CSF protein, low to low normal CSF glucose, and elevation of CSF white cell count associated with a neutrophilic shift. There is a higher rate of Gram-negative bacteria involvement in postoperative meningitis. In the developed world the most common causative organism is *S. aureus*. However, there are geographical variations such that in an Indian series the most common organisms were Gram-negative bacillus, pseudomonas aeruginosa, and klebsiella (Kourbeti et al., 2007; Dashti et al., 2008).

Appropriate antibiotic treatment, either intravenous or oral, is required for postoperative meningitis. In the first instance empirical antibiotic typically consists of a combination of vancomycin with third-generation of cephalosporins. If CSF sampling allows culture and sensitivity of the causative organism, antibiotic treatment should be tailored accordingly.

Ventriculitis remains a common problem in neurosurgery following temporary CSF diversion with external ventricular drains. A smaller group of patients develop ventriculitis as a result of rupture of a cerebral abscess into the ventricle. In this circumstance, the large bacterial load confers a poor prognosis.

Modern neurosurgical practice recommends antibiotic-coated or silver-lined ventricular catheters to decrease the incidence of ventriculitis (Keong et al., 2012; Athanasios et al., 2015).

Other factors that are associated with decreasing incidence of EVD infection include a standardized protocol for insertion, long subcutaneous tunnelling (>15 cm), minimal handling by both medical and nursing staff, aseptic technique for sampling of CSF, and decreasing frequency of CSF sampling (Lwin et al., 2012; Kubilay et al., 2013). Routine CSF sampling has not shown to be necessary for early detection of CSF infection (Hader and Steinbok, 2000).

Ventriculoperitoneal shunt (VP shunt) infection is defined as either early (less than 6 months) or late (more than 6 months). Patients usually present with non-specific symptoms such as fever, nausea and vomiting, irritability, change in mental states. VP shunt infection may also present as shunt malfunction. The most common pathogens involved in VP shunt infection are skin flora such as *S. epidemidis* and *S. aureus*.

The principles of treatment are removal of the infected shunt, accompanied by the use of systemic antibiotic with the use of temporary CSF diversion such as external ventricular drain, lumbar drain, or lumbar punctures. Antibiotics are continued until CSF polymorphs fall to normal allowing subsequent implantation of a new ventriculoperitoneal shunt. Pure medical treatment with antibiotics alone are less effective (James et al., 1980; Tamber et al., 2014).

Intracranial pressure monitoring and craniectomy in meningitis and encephalitis

There are no firm guidelines on the use of intracranial pressure monitoring for patients with meningitis and encephalitis. However, meningitis and encephalitis can result in severe cerebral oedema and cortical pseudolaminar necrosis with resultant raised ICP and herniation (Fig. 98.5). A recent study in Sweden compared an ICP intervention group versus a control group of patients with acute bacterial meningitis, showing significant decreased mortality in the intervention group (relative risk reduction of 68%); better neurological recovery was also seen in the ICP intervention group (Sala et al., 2009; Glimåker et al., 2014). There is also another reported case of severe cerebral oedema resulting from tuberculous meningitis which responded well with ICP monitoring and institution of ICP controlling measure, and the patient subsequently had a good neurological recovery (Trendelenberg et al., 2011).

Decompressive craniectomy in encephalitis is uncommon and may be considered in salvage situation where ICP is refractory to medical treatment. It is suggested that the long-term neurological outcome in herpes simplex encephalitis patient that received craniectomy does not differ significantly from patient which did not require craniectomy (Youenn et al., 2015; Algahtani et al., 2016).

Postoperative neurosurgical infections

Postoperative surgical site infection (SSI) is strictly defined by the Centre for Disease Control (CDC). SSI is divided into superficial incision SSI, deep incision SSI, and organ/space SSI.

Postcraniotomy SSI is a substantial cause of morbidity and mortality in postoperative neurosurgical patients. The incidence of postoperative neurosurgical SSI is between 3% and 5% depending on the series. Postcraniotomy SSI includes a wide spectrum from simple wound dehiscence and breakdown, underlying scalp infected collections, skull flap osteomyelitis, to subdural empyemas or intracerebral abscesses. The management of each individual condition are dealt with in the relevant sections.

There are several risk factors which are associated with increased risk of postcraniotomy SSI. These includes multiple operations, evidence of CSF leak, increased duration of surgery, altered sensorium, presence of comorbidities such as diabetes, and concurrent use of corticosteroids (Jiang et al., 2016). A study from Malaysia showed that patients with perioperative ASA 2 and clean contaminated wounds are significant risk factors for development of SSI (Buang and Haspani, 2012). The predominant bacteria identified in postcraniotomy SSI are *Staphylococcus aureus*, followed by *Acinetobacter* and *Enterobacter* (Buang and Haspani, 2012).

Numerous recommendations have been made for prevention of SSI, an exhaustive discussion of which is available on WHO website on Global Guidelines on the Prevention of Surgical Site Infection 2016—http://www.who.int/gpsc/ssi-prevention-guidelines/en/. Prophylactic antibiotics are widely regarded as a key preventative measure. This requires selection of appropriate antibiotic, administration within 1 hour preincision, and discontinuation within 24 hours after surgery. Other measures include the careful handling of soft tissues, good haemostasis, and a well approximated wound closure. There is some suggestion that the use of betadine irrigation decreases the risk of postop craniotomy SSI (Patel et al., 2014).

Superficial infections of the scalp are the commonest form of SSI. Typical manifestations include local erythema, swelling, and tenderness, which over time will progress to frank wound breakdown with formation of pus. Systemic symptoms such as fever, tiredness, and lethargy are generally late signs. Symptoms such as neck stiffness, altered mental status or new focal deficits warrants an investigation to ensure there is no extension of the superficial infection into the deeper structures for example subdural empyema or meningitis. In simple uncomplicated cases, treatment is predominantly with antibiotics, in particular with good Gram-positive cover. Surgical debridement of

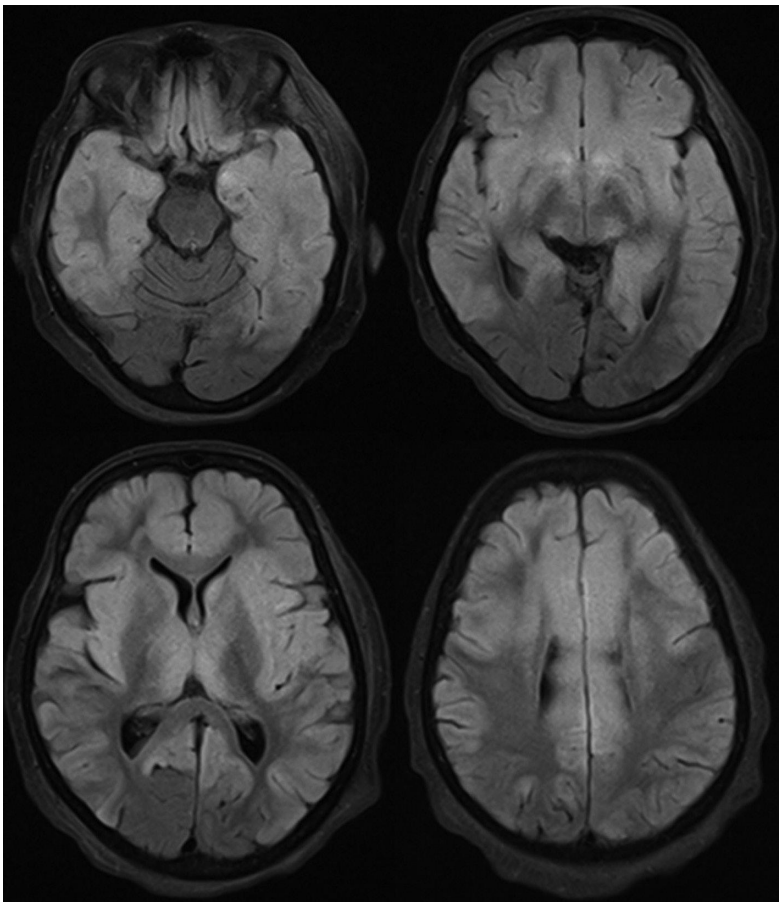

Fig. 98.5 MR imaging in herpes simplex virus (HSV) encephalitis showing extensive involvement of frontotemporal lobes and basal ganglia resulting in severe cerebral oedema and pseudolaminar necrosis (Algahtani et al., 2016).

the skin flap may be required in situations where there is an extensive infection or presence of underlying scalp collections.

Spinal infection

Nicholas Haden and Edward White

Introduction

Spinal infections are rare, but their incidence is rising and they are associated with significant morbidity and mortality. Delays in diagnosis and treatment initiation due to their rarity and non-specific presenting symptoms remain a significant problem. A high index of suspicion and aggressive management are critically important in optimizing patient outcomes. This chapter provides an overview of spinal epidural and paraspinal abscesses, discitis, and vertebral osteomyelitis (collectively referred to as spondylodiscitis), and post-operative spinal infections.

Spinal epidural and paraspinal abscesses

Spinal epidural abscess (SEA) is defined as a suppurative infection within the extradural space. SEA represents a significant diagnostic challenge in view of its rarity, non-specific presentation, and propensity to progress rapidly to irreversible paralysis and severe sepsis.

Epidemiology

SEA is rare with an incidence of 1.96 cases per 10 000 hospital admissions. The average age of patients diagnosed with SEA is 57.5 years and a slightly higher incidence is observed in men (Reihsaus et al., 2000). The incidence is increasing due to improved diagnostic imaging with MRI, an ageing population, the rising incidence of HIV, and intravenous drug use.

Pathophysiology

SEA arise within the epidural space in the locations containing the most epidural fat (dorsal and lateral to the dura), which due to its low vascularity is hypothesized to be susceptible to bacterial infection. The pathophysiological mechanisms underlying spinal cord dysfunction secondary to SEA are unclear. A combination of mechanical cord compression and vascular compromise are likely to be responsible and prolonged cord compression may lead to irreversible cord ischaemia.

Anteriorly placed SEA is uncommon and most often occur secondary to spondylodiscitis. SEA occur most commonly in the thoracic spine, followed by the lumbar spine and the cervical spine, although on average a SEA will extend the length of several vertebral bodies. Bacteria may gain access to the spinal epidural space via three routes, although in 30% of cases no source is identified (Darouiche et al., 1992):

Haematogenous

Haematogenous spread is responsible for approximately 50% of cases. Potential sources include:

i. Skin infection (most common)
ii. Intravenous drug use
iii. Infected vascular access
iv. Bacterial endocarditis
v. Urinary tract infection
vi. Respiratory tract infections
vii. Pharyngeal or dental abscess

Direct extension

Direct extension of infection into the extradural space is responsible for approximately one-third of cases. Potential sources include:

i. Spondylodiscitis
ii. Psoas abscess
iii. Decubitus ulcer
iv. Pharyngeal infection causing cervical SEA
v. Mediastinitis causing thoracic SEA
vi. Penetrating trauma
vii. Pyelonephritis with perinephric abscess

Intraoperative inoculation

i. Open surgical procedures

Risk factors

In common with other infections, SEA is more common in patients with diabetes mellitus, therapeutic immunosuppression, malignancy, HIV, alcoholism, and chronic renal failure, as well as in intravenous drug users. A history of trauma is observed in minority of patients and may act as a precipitant for bacterial entry into the extradural space.

Clinical features

The classical triad of back pain, fever, and a neurological deficit is observed in a minority (13%) of patients on initial presentation, although in 75% of patients there is a significant diagnostic delay (Davis et al., 2004). In a meta-analysis of 915 patients, back pain was the most common symptom associated with SEA (71%) followed by fever (66%) and a neurological deficit (63%). Less common symptoms and signs include radiculopathy (20%), focal tenderness (17%), headache (3%), and neck stiffness (3%). Postoperative SEA tends to present in a much vaguer manner as fever and neurological deficits are uncommon (Reihsaus et al., 2000). In view of the rapid and potentially irreversible progression to paralysis, a high index of suspicion is required.

Investigations

Laboratory studies

Inflammatory markers including white cell count, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are typically elevated. A leucocytosis is seen in 60–80% of patients and the mean CRP in a series of 25 patients was 150 mg/litre (Soehle and Wallenfang, 2002).

Imaging studies

MRI is the diagnostic study of choice as it distinguishes SEA from differential diagnoses including transverse myelitis, cord ischaemia, spinal tumours, and disc prolapses, as well as identifying concurrent osteomyelitis and discitis (Fig. 99.1). In patients in whom MRI is contraindicated, computed tomography (CT) with contrast and CT myelography are useful imaging modalities, albeit with lower sensitivity and specificity.

Microbiological studies

Identification of the causative organism is key to the management of SEA. Pus samples may be obtained following surgical drainage or CT-guided abscess aspiration in cases of non-operative management. Pus cultures are positive in 90% of cases, compared with 60% of blood cultures. The most common organism is *Staphylococcus aureus* (60%) followed by Gram-negative bacilli (including *Escherichia coli, Pseudomonas aeruginosa*, and *Klebsiella*). Infections are polymicrobial in 10% of cases (Sendi et al., 2008). The diagnostic yield of microbiological cultures is reduced if antibiotics are administered prior to sampling, although in clinical practice the benefits of identifying the causative organism must be weighed carefully against the risks of clinical deterioration, if there is a delay in obtaining pus.

Treatment

The rarity of SEA and the potentially poor outcome associated with conservative management make the conduct of a randomized controlled trial impractical and evidence is only available from several case series. Broadly speaking, treatment may be surgical drainage and targeted antibiotic therapy or antibiotic therapy alone, albeit guided by cultures. The principle difficulty associated with conservative management is that a rapid neurological deterioration may be observed in neurologically intact patients despite appropriate antibiotic therapy.

Surgical treatment is recommended unless:

i. Surgical and anaesthetic risks are prohibitive
ii. There is involvement of an extensive length of spinal cord
iii. There is complete paralysis of greater than 48 hours duration
iv. The patient is neurologically intact

If surgical decompression is not performed, CT-guided aspiration of the abscess is indicated in order to identify the causative organism and close observation is mandated to ensure that rapid neurological deterioration does not occur. Predictors of failure of conservative management include:

i. Age greater than 65 years
ii. Diabetes mellitus
iii. Bacteraemia (especially methicillin-resistant *Staphylococcus aureus*, MRSA)

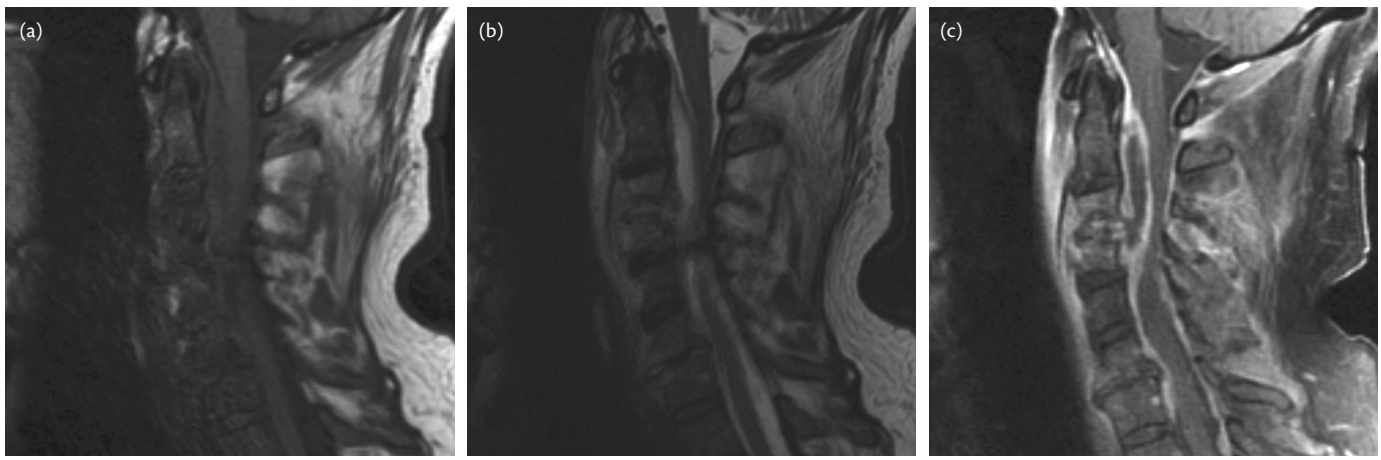

Fig. 99.1 MR imaging of spinal epidural abscesses. Sagittal cervical MRI demonstrating the characteristic features of SEA. On T1-weighted imaging (A), SEA are visible as a hypo- or isointense collection, whereas on T2-weighted imaging (B), SEA are hyperintense. Three patterns of enhancement are observed in the form of dense homogenous enhancement, inhomogeneous enhancement and rim enhancement (as seen in image C). However, in the acute stage when the collection is mainly pus without granulation tissue, little enhancement may be seen. Poor prognostic factors on MRI include (Tang et al., 2002): greater than 50% narrowing of spinal canal; peripheral enhancement; signal change within the spinal cord; SEA greater than 3 cm in length.

iv. Neurological deficits
v. White cell count greater than 12.5×10^9
vi. CRP more than 115 (Kim et al., 2014)

The goals of surgical intervention are debridement of granulation tissue and drainage of pus to alleviate cord compression and to obtain a sample for microbiological analysis. As most SEA are posterior, laminectomy or laminotomy with irrigation of the extradural space using a catheter is suitable in most cases. If the SEA is associated with an implanted spinal cord implant, explantation is mandatory. In extensive or anteriorly located SEA, osteomyelitis may be present within the vertebral body. In these cases, instability may develop after laminectomy and consideration should be made for supplemental posterior instrumented fusion and/or extracavitary approaches to the vertebral body with vertebral reconstruction using an expandable cage or strut grafting.

Typically antibiotic treatment involves a third-generation cephalosporin plus vancomycin, until MRSA is ruled out. Subsequent antibiotic therapy is modified once culture results become available. Antibiotic therapy is typically intravenous in the first instance in view of improved bioavailability compared with oral treatment and antibiotic therapy is usually necessary for a minimum of 6 to 8 weeks. Prolonged treatment may be necessary in the context of spondylodiscitis or immunosuppression.

Outcome

Spontaneous SEA is associated with a mortality of 16%, paralysis in 15%, a residual neurological deficit (excluding paralysis) in 26%, and a complete recovery in 43% (Reihsaus et al., 2000). Mortality is usually due to the consequences of paralysis or the source of infection. Poor prognostic markers include the duration and severity of the pretreatment neurological deficit, MRSA infection, steroid use, HIV, thrombocytopenia, cervical SEA, diabetes mellitus, rheumatoid arthritis, and age over 50 years.

Spondylodiscitis

There is a significant overlap between infection of the intervertebral disc (discitis) and vertebral osteomyelitis. Together these are frequently referred to as spondylodiscitis. Spondylodiscitis frequently coexists with SEA. Spondylodiscitis in the cervical spine is associated with SEA in 90% of cases, whereas thoracic and lumbar spondylodiscitis are associated with SEA in 33% and 24% of cases, respectively (Hadjipavlou et al., 2000).

Spondylodiscitis can be classified as pyogenic, granulomatous (tuberculous and fungal infections) or parasitic in nature. Pyogenic spondylodiscitis may be further classified as primary or secondary (postprocedural). Spondylodiscitis most commonly involves the lumbar spine (58%) followed by the thoracic (30%) and then cervical spine (11%) (Mylona et al., 2009).

Epidemiology

The annual incidence of spondylodiscitis has been reported as 2.4 per 100 000 and there is evidence that the incidence is rising, perhaps due to ageing population, the increasing use of spinal instrumentation and the rising prevalence of intravenous drug abuse. There is a bimodal distribution of cases, peaking in the second decade of life with a much higher peak after the sixth decade of life. Males are affected approximately twice as commonly as females in this older age group (Skaf et al., 2010).

Pathophysiology

Bacteria can infect the spine through the haematogenous route, intraoperative inoculation, or direct spread from sites of adjacent infection, which is rare. In childhood, extensive vascular anastomoses exist that extend into the intervertebral disc. Consequently, septic emboli are unlikely to cause an osseous infarcts and infection is typically localized to the disc. In the third decade of life, these anastomoses involute, creating end arteries. Septic emboli may then cause large osseous infarcts with infection involving the disc and adjacent bone. This may progress to pathological fractures and significant deformity.

In view of the comparatively poor blood supply to the posterior spinal elements, pyogenic osteomyelitis does not usually affect the lamina, pedicles, or transverse and spinous processes, and involvement of these structures should raise the possibility of tuberculous or fungal osteomyelitis.

A distant septic source is identifiable in approximately half of cases of spondylodiscitis. Sources include the urinary tract (17%), bacterial endocarditis (12%), skin and soft tissue (11%), intravascular devices (5%), gastrointestinal tract (5%), respiratory tract (2%), and oral cavity (2%) (Gouliouris et al., 2010). Direct inoculation most commonly occurs following spinal surgery, lumbar puncture and epidural anaesthesia and accounts for approximately 30% of cases.

Worldwide, tuberculosis is the most common cause of spinal infection (Pott's disease) and arises due to haematogenous spread of *Mycobacterium tuberculosis* from a primary focus. Excluding tuberculous cases, *Staphylococcus aureus* is the most frequent cause of spondylodiscitis accounting for between 32% to 67% of cases. Methicillin-resistant *S. aureus* (MRSA) spondylodiscitis remains extremely rare. The second most common cause of pyogenic spondylodiscitis are Enterobacteriaceae (most commonly *Escherichia coli*), which account for 7–33% of cases (Gouliouris et al., 2010). Streptococci and enterococci account for 5–20% of cases of spondylodiscitis and are most commonly associated with bacterial endocarditis (Mylona et al., 2009).

Risk factors

The majority of patients with spondylodiscitis have at least one of the following risk factors (Mylona et al., 2009):

i. Diabetes mellitus (24%)
ii. Intravenous drug abuse (11%)
iii. Immunosuppression (7%)
iv. Malignancy (6%)
v. Alcoholism (5%)
vi. Rheumatic disease (5%)
vii. Liver cirrhosis (4%)
viii. Renal failure (4%)
ix. Previous radiation or fracture to vertebra

Clinical features

Pain is the most common symptom of spondylodiscitis affecting more than 90% of patients. Back pain is typically unremitting and

worse at night and on movement. Fever occurs in approximately 50% of patients, although this is less frequent in patients with tuberculosis. Neurological deficits and radiculopathy occur in approximately one-third of patients (Mylona et al., 2009). The onset is usually insidious and non-specific, particularly in atypical infections, and due to the rarity of spondylodiscitis and the frequency of mechanical back pain, there is often a significant diagnostic delay. This diagnostic delay is often longer in cases of TB, which has an insidious onset, but in its later stages can lead to epidural and paravertebral collections, neurological deficits, and severe deformity.

The most common sign of spondylodiscitis is spinal tenderness and there may be associated paraspinal muscle spasm and impaired spinal movements. Rare presentations include a painful gibbus deformity, clinical features of a psoas or retropharyngeal abscess, sinus formation, and a spinal mass. Symptoms in children include irritability, refusal to move and abdominal pain (Gouliouris et al., 2010).

Investigations

Laboratory studies

The white blood cell count is elevated in 35% of cases, but is often normal in older people and immunocompromised. CRP is more sensitive, being elevated in more than 90% of cases. Approximately 70% of patients are anaemic and 50% have a raised serum alkaline phosphatase (Gouliouris et al., 2010).

Microbiological studies

In cases of suspected spondylodiscitis, blood and urine cultures should be obtained in addition to a sample from the involved disc or vertebral body. Blood cultures are positive in approximately 50% of cases and there is a concordance of 85% with disc or vertebral body culture results. This diagnostic yield is probably higher with more virulent organisms and in pyrexial patients. CT-guided, direct culture of the infected disc or vertebra, which has a diagnostic yield of around 70%, and in 24% of cases more than one organism is identified (Hadjipavlou et al., 2000). Tissue Gram stain, both aerobic and anaerobic cultures, fungal and TB cultures, and TB PCR are mandatory. Histology is also helpful in distinguishing granulomatous from pyogenic spondylodiscitis and ruling out an underlying tumour.

Imaging studies

Plain radiographs may demonstrate endplate irregularity progressing to endplate erosion, disc space narrowing, and progressive loss of vertebral height and deformity. These changes start to develop around 3–6 weeks after symptom onset. Reactive bone sclerosis starts to appear at around 8–12 weeks and may progress to exuberant osteophyte formation and spontaneous fusion. Nevertheless, the sensitivity and specificity of plain radiographs remains low with values of 82% and 57%, respectively (Modic et al., 1985). CT demonstrates these changes earlier and is invaluable in undertaking biopsies for microbiological and histological analysis.

MRI is the imaging study of choice with both high sensitivity (96%) and high specificity (92%), as well as the ability to delineate epidural and paraspinal collections (Dagirmanjian et al., 1999) (**Figs. 99.2** and **99.3**).

Radionuclide bone scanning with technetium-99m is highly sensitive (90%) in the first few days of infection, but less specific (78%), with degenerative changes resulting in false positives. In cases where there is diagnostic doubt, fluorine-18 fluorodeoxyglucose positron emission tomography (FDG-PET) is a useful adjunct as it is capable of distinguishing infection from degenerative changes.

The value of routine MRI to monitor treatment response is less certain. Radiological markers of resolution include bony restoration and loss of contrast enhancement. However, these changes often appear late and MRI scans obtained within 4–8 weeks of treatment initiation often show an increase in enhancement and marrow oedema.

Treatment

The key elements of treatment include eradication of infection, alleviation of pain, and preservation of spinal structure and function. Antibiotic therapy should be initiated after appropriate tissue samples have been obtained, although in the presence of severe sepsis or neutropenia, empirical antibiotics should be started immediately.

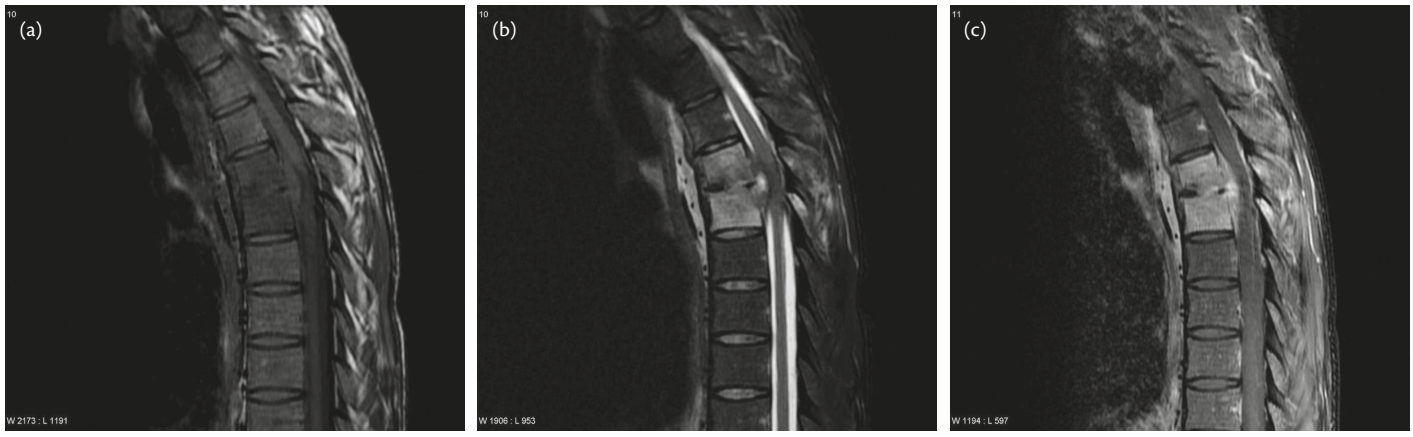

Fig. 99.2 MR imaging of spondylodiscitis. Sagittal thoracic MRI demonstrating the typical features of spondylodiscitis. Initial MR abnormalities are due to inflammation and oedema in the vertebral body and disc space. These changes are characterized by hypointensity in the bone marrow on T1-weighted imaging (A). Hyperintensity in the bone marrow and disc space is typically seen on short tau inversion recovery (STIR) and T2-weighted imaging (B). Enhancement develops initially at the end plate-disc interface and progresses into the vertebral body as bony destruction progresses (C). This enhancement improves the diagnostic utility of MRI and helps distinguish infection from modic 1 degenerative changes.

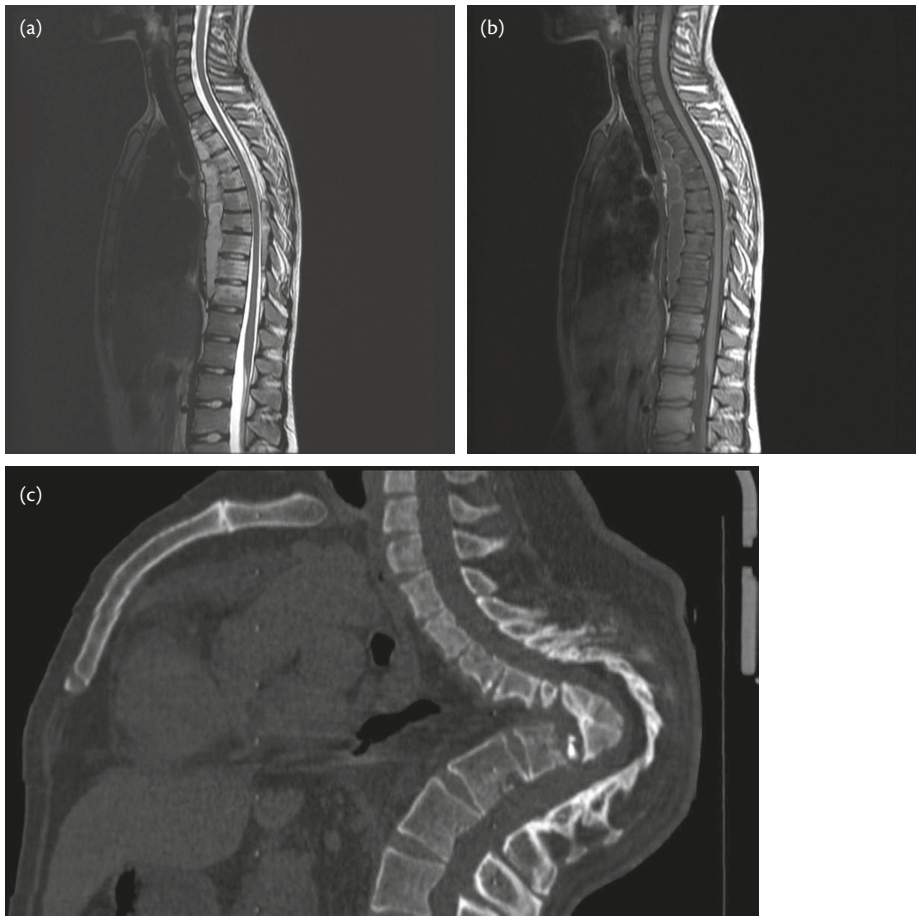

Fig. 99.3 Imaging findings in spinal tuberculosis. Sagittal T2 (A) and T1-weighted (B) MR images and sagittal CT scan (C) demonstrating typical features of spinal TB. Classically, spinal TB involves the vertebral body, sparing the posterior elements, but involving multiple levels as infection spreads in a subligamentous manner, under the anterior longitudinal ligament, potentially causing a prevertebral abscess (A, B). Consequently, irregularity of the anterior vertebral body is a characteristic early radiological sign. Progression to deformity (C) and large paraspinal collections is common.

Once the causative organism has been identified, appropriately targeted, intravenous antibiotics should be administered.

In an open-label, non-inferiority, randomized, controlled trial, Bernard et al (2015) demonstrated that 6 weeks of antibiotics (intravenous for approximately the first 14 days) was not inferior to 12 weeks of antibiotics at 1-year follow-up. Antituberculous chemotherapy for spinal TB necessitates prolonged treatment and identification of drug-resistant strains of Mycobacterium tuberculosis.

The role of spinal immobilization is less certain. If there has been significant vertebral destruction, bed rest is recommended. In cervical spondylodiscitis, a hard collar may be advisable. Once pain has settled, patients with thoracic or lumbar spondylodiscitis should be mobilized in a thoracolumbar sacral orthosis (TLSO) or a lumbar sacral orthosis (LSO).

Indications for surgical intervention include the presence of spinal instability characterized by progressive deformity or substantial bone loss, significant neurological deficits due to neural compression, failure to respond to conservative measures and intractable pain. Percutaneous drainage is often preferred to surgical drainage of large paravertebral abscesses.

A multitude of surgical techniques may be used in the management of spondylodiscitis. In the presence of a dorsally located SEA, a laminectomy may be appropriate, although due to the tendency for spondylodiscitis to involve the vertebral body and disc, this may lead to spinal instability. In the cervical spine, anterior approaches are favoured to debride infected bone. Multilevel corpectomies may be supplemented with posterior instrumentation. In the thoracic spine, the rib-cage acts to maintain stability and therefore immobilization with the use of an appropriate orthosis may negate the need for surgical stabilization. If, however, decompression and debridement are necessary, transthoracic, or posterolateral approaches may be necessary and may need to be supplemented with posterior stabilization.

Maintenance of structural integrity may be achieved using a variety of techniques including the use of autologous bone graft and titanium mesh, structural autografts such as tricortical rib and fibula, and allografts. Concerns regarding the implantation of hardware within an infected field are not borne out in the literature.

Outcome

The mortality of spondylodiscitis is approximately 5%, usually due to severe sepsis (Gouliouris et al., 2010). Approximately one-third of patients have a residual neurological deficit. The relapse rate has been reported as 14% with the majority recurring within one year. Relapse was more common in the presence of recurrent bacteraemia, chronic sinuses, and paravertebral abscesses. Risk factors for an adverse clinical outcome include a diagnosis delayed by

more than 2 months, motor weakness and a nosocomial infection (McHenry et al., 2002).

Postoperative wound infection

Postoperative surgical site infection (SSI) following spine surgery has been reported to occur in 1.2% of patients undergoing basic spinal decompression surgery and 2.4% in patients undergoing fusion surgery. This rate is even higher in patients sustaining traumatic spinal injuries where infection rates of up to 10% have been reported, perhaps due to prolonged bed rest, exposure to nosocomial infections and the development of a catabolic metabolic state following the injury (Hegde et al., 2012).

Risk factors

See **Box 99.1** for the risk factors for postoperative spinal infections.

Pathophysiology

Factors implicated in the development of SSI may be microbiological in nature or relate to the patient or surgical procedure. The most common causative organism is *Staphylococcus aureus*, although other common organisms include *Staphylococcus epidermidis, Enterococcus faecalis*, and *Pseudomonas aeruginosa* (Weinstein et al., 2000). Most commonly organisms enter the wound intraoperatively, although haematogenous spread may occur. The key elements in preventing SSI are meticulous attention to aseptic technique and the use of prophylactic antibiotics.

There are numerous patient-specific factors that have been shown to predispose to infection. Intraoperative factors that increase the likelihood of an SSI include the duration of surgery, the use of instrumentation, revision surgery, excessive staff within theatre and possibly the use of operating microscopes or loupe-magnification (Hegde et al., 2012). Potential techniques for minimizing the risks of infection include avoiding excessive use of electrocautery, regular release of retractors, debriding wounds at the end of the procedure and the use of antibiotic wound irrigation and closed suction drains.

Box 99.1 Risk factors for postoperative spinal infections

Preoperative

1. Advanced age
2. Obesity
3. Diabetes mellitus
4. Smoking
5. Previous chemotherapy or radiotherapy
6. Preoperative incontinence
7. Preoperative paralysis
8. ASA grade 3 or 4
9. Spinal trauma

Intraoperative

1. Posterior cervical surgery
2. Multilevel surgery
3. Tumour resection
4. Intraoperative transfusion

Postoperative

1. Incontinence
2. Transfusion
3. Steroid usage

Source data from Olsen et al., 2003. http://thejns.org/doi/abs/10.3171/spi.2003.98.2.0149

Clinical features

Typical features of infection include back pain, wound tenderness, erythema, and discharge. Severe infection may cause fever, hypotension, and confusion. Indolent infections from organisms such as *Propionibacterium acnes* may cause more vague symptoms of pain with possible pseudarthrosis and hardware loosening. Clinical features may also be suggestive of concurrent spondylodiscitis or SEA with associated neurological deficits.

Investigations

Laboratory tests

CRP measurements are key in evaluating patients with a suspected SSI. Normally the CRP normalizes within two weeks of surgery. White cell counts are often normal and superficial cultures are unreliable due to contamination from skin flora. Consequently, intraoperative tissue cultures are invaluable in making the diagnosis and guiding antibiotic treatment (Hegde et al., 2012). Revision spinal surgery often merits obtaining intraoperative cultures to rule out low-grade infection.

Imaging studies

CT may demonstrate implant loosening with lucency around instrumentation and evidence of discitis. Contrast-enhanced MRI is the imaging modality of choice in detecting SSI and concurrent spondylodiscitis or SEA. Nevertheless, interpreting postoperative MR imaging can be challenging due to metal artefact and the expected postoperative changes following discectomy, which include subtle enhancement within the intervertebral disc space and annulus, with endplate hypointensity on T1-weighted imaging and hyperintensity on T2-weighted imaging. Spondylodiscitis tends to produce more florid, circumferential enhancement of the intervertebral disc. Bone scans are not helpful as they will show increased uptake at sites of reactive bone formation for up to one year following surgery.

Treatment

Superficial abscesses may be managed by incision, drainage, wound debridement, and antibiotics. Indications for surgical drainage of SEA have previously been discussed. Large paraspinal abscesses may benefit from CT-guided aspiration. Infections with virulent organisms or in the immunocompromised may require multiple wound washouts.

In the context of infected fusion cases, copious irrigation, removal of loose bone graft and metalwork is mandatory. Infection can often be successfully managed in the presence of interbody cages and posterior instrumentation (Weinstein et al., 2000). When multiple wound washouts are necessary, some authors advocate implantation of antibiotic-impregnated beads into the wound (Hegde et al., 2012).

In the context of a late infection when fusion has already occurred, instrumentation removal is beneficial in clearing the infection.

Isolated postoperative discitis is effectively managed with a course of intravenous antibiotics. These may be guided by cultures obtained from a CT-guided, disc space biopsy, which has a high diagnostic yield. Bracing may be used for patient comfort. Resolution of infection is often associated with spontaneous fusion of the disc space. Rarely, in cases of failed conservative management where there is destruction of the vertebral body, progressive deformity, neurological deficits, or SEA, lumbar discectomy and interbody fusion or vertebral reconstruction may be required.

Controversy: The role of antibiotics in discogenic back pain

There is a growing body of evidence suggesting that there is an association between symptomatic disc degeneration, modic changes on MRI and disc space infection by anaerobic organisms of low virulence such as *Propionibacterium acnes and Corynebacterium propinquum* (Stirling et al., 2001). These studies are controversial as it is possible that positive cultures obtained in these studies were due to perioperative contamination with skin commensals. Nevertheless, a double-blind, randomized, placebo-controlled trial (n = 162), demonstrated a significant improvement in low back pain and leg pain in patients with a history of lumbar disc prolapse and type 1 Modic changes on MRI, following treatment with amoxicillin-clavulanate aimed at eradicating these organisms (Albert et al., 2013).

Significant questions still remain regarding the validity of the findings from this trial. Specifically, it is unclear as to the number and distribution, between treatment groups, of patients who had undergone surgery for their lumbar disc prolapse. It is conceivable that bacterial disc space contamination may have occurred during surgery, leading to a low-grade discitis, which may have subsequently been responsive to antibiotics. At 1-year follow-up, two-thirds of patients in the treatment group still had significant pain and patients treated with placebo had unusually stable measurements of pain severity and minimal placebo effect was observed. Finally, it is unclear as to whether patients were adequately blinded to their treatment.

In conclusion, there is a need for further studies evaluating whether there is a link between low-grade disc infection, modic changes, and symptomatic disc degeneration. Specifically, an appropriately designed and powered, multicentre, placebo-controlled, randomized trial is necessary to determine whether there is a role for antibiotic treatment in these patients.

trans-sphenoidal
hypophysectomy 345
trans-Sylvian-transcortical-transventricular keyhole hemispherotomy 964, 965
transverse myelitis 687–9
traumatic aneurysms 561–2
traumatic brain injury
aetiology 475
anaemia 499
anaesthesia 63–4
apolipoprotein E 493
arteriovenous fistula 521–2
autoregulation 487–9, 490–1
beta-amyloid deposition 493
biomarkers 478
biomechanics 483–4
cardiorespiratory function 497–9
carotid dissection 514–15, 521
cerebral blood flow 486, 487–8, 492, 503–4, 504*t*
cerebral contusions 486
cerebral metabolism 487–91
cerebral microdialysis 504*t*, 506
cerebral oxygenation monitoring 504–5, 504*t*
cerebral perfusion pressure 503
cerebrovascular reactivity 503
children 999–1004
classification 476, 484–7
clinical severity 477–8
coagulopathy 499
Common Data Elements 494
cortical spreading depression 493, 506
coup/contre-coup contusions 483–4
cranial nerve injuries 522
cranioplasty 515–16
craniotomy 510–11
CSF leaks 514, 523, 524*f*, 525–6
decompressive craniectomy 511–13, 527
definition 475
depressed skull fractures 513, 522–3
diffuse axonal injury 486
early complications 521–3
early management 497, 498*f*
economic costs 479
EEG/ECoG 504*t*, 506
electrolytes 500
endocrine disturbances 500
epidural haematoma 484–5
external ventricular drain 510
extracranial injuries 478
extradural haematoma 484–5, 510
glutamate-mediated excitotoxicity 489
glycaemic control 499
growing skull fractures 527
hearing loss 522
hydrocephalus 515, 525
hyperaemia 492
hypotension 497, 498–9
hypoxia 497–8
incidence 475–6
infections 526–7
intensive care management 497–507
intracerebral haemorrhage 511
intracranial pressure 491–2, 501–3, 504*t*, 509
intraventricular haemorrhage 485–6
ischaemic injury 492–3
late complications 523–7
Marshall CT classification 478
mechanism of injury 476–7
mild (concussion) 486–7, 531–5
mortality 476
multimodality neuromonitoring 503–6
neurorehabilitation 527–8
non-neurological organ system dysfunction 500–1
nutritional support 500
oedema 491
optic nerve injury 522
otic capsule injury 522
outcome assessment 478–9
pathophysiology 483–95
penetrating injury 487, 514
pituitary dysfunction 318, 525
pneumocephalus 523
polytrauma 497
post-traumatic encephalopathy 527
prevalence 476
prognostic risk 478
quality of life measures 479
secondary injury 489–93
seizures 493, 500, 523, 525
skull base fractures 513, 525–6
sodium disturbances 500*t*
speech and language therapy 527–8
subarachnoid haemorrhage 485, 521
subdural haematoma 485, 510–11, 527
surgical management 509–19
targeted temperature management 499
venous thromboembolism prophylaxis 71, 500
ventriculostomy 510
vertebral dissection 514–15, 521
trigeminal neuralgia 909, 911–21
anatomical findings 914–15
atypical 911
balloon compression 917*t*, 920
clinical presentation 911
decision-making 918*f*
diagnosis 911, 913–14
glycerol neurolysis 917*t*, 920
microsurgical vascular decompression 915–17, 917*t*
radiofrequency thermorhizotomy 917*t*, 917–18, 919*f*
stereotactic radiosurgery 917*t*, 920
typical 911
trigeminal schwannoma 264, 292
tuberculoma 1118
tuberous sclerosis complex 454–6, 462
tumefactive multiple sclerosis 467–8
tumour suppressor genes 89
tumour treating fields 100
Turcot syndrome 354, 354*t*

ulnar neuropathy 28*b*, 832
ultrasonic aspirators 50–1
ultrasound 39
intraoperative 54
MR-guided focused 112
uncinate fasciculus 164
unconscious patient examination 12
unfractionated heparin 71
unifacetal fracture dislocations 792–3, 798
Unified Parkinson's Disease Rating Scale (UPDRS) 875
Unterberger's test 23, 283
upper limb examination 24–7
upper motor neuron 22–3
urological function
normal pressure hydrocephalus 1087
spinal dysraphism 987

vaccines 158–9
vagal nerve stimulation 963, 1051–2
vancomycin powder 1115
vascular anatomy 539–54
vascular imaging 39–40
vascular physiology 554–7
vascular space occupancy imaging 41
vaso-glossopharyngeal neuralgia 909, 921
vasospasm 569–72, 586
vein of Galen 439
malformations 1038–9
velocity of diametric expansion 78
venous access 59
venous air embolism 65
venous stenting 1098
venous thromboembolism
neurosurgery 71, 169
spinal cord injury 816
spinal surgery 666
traumatic brain injury 500
ventral horn 679
ventral pontine syndrome 617
ventral stream 164
ventricular access devices 1027–9
ventricular taps 1027
ventriculitis 1124
ventriculomegaly 1065–7
ventriculoperitoneal shunts 1031–4, 1075, 1076*b*, 1124
ventriculostomy 510
ventriculosubgaleal shunts 1027–9
Vernet syndrome 272*t*, 523*t*
vertebral anatomy 669–72
vertebral arteries 545
vertebral dissection 514–15, 521
vertebrobasilar insufficiency syndromes 616–17
vertebroplasty 716
vertigo 262, 283, 909, 922–3
Vesalius 4
vestibular examination 23
vestibular schwannomas 255–63
aetiology 255, 258
audiometry 284
epidemiology 255
facial nerve function 262–3, 284–5
genetics 255
growth of residual tumours 259–60
